There have been arch-conspirators who suggested to their followers criminal acts. In all of our ancient, mediæval, and modern literature, in all the records of criminal law, we can see that there were arch-conspirators and their followers; people who suggested crime and those who committed it, and whenever any of these were convicted they were punished according to law. The fad of hypnotism had not been born, and they were suffered to die for their murders. Has it been an injustice to murderers in all the ages of the past that they have been allowed to die on the scaffold and by the guillotine because they did not possess the broad definition of a word from the Greek language meaning sleep?

We act upon good or bad suggestion according to our training. A man looks in through the windows of a bank, sees a large stack of bills and gold; it suggests to him that if he could break into the place at night, and open the vault, it would bring him ease and comfort. He follows the suggestion and commits the burglary. Should he be exonerated because he was hypnotized by inanimate things? Another sees a man put a large bundle of bills into his pocket and start for his home in the distance. It suggests to him that he could rap him on the head with a club and appropriate the money for his own use, and he does so. Suggestion has hypnotized him to do the act. A lady and a gentleman become acquainted; the conversation and manners of the gentleman suggest to her that he would make a good husband; circumstances culminate and they are married. Later a quarrel follows, and then it occurs to the woman that she was hypnotized and forced to marry. Should she be granted a divorce on these grounds? Truly so, if a murderer is cleared.

Horses are almost universally hypnotized when a barn takes fire. Invariably they will not leave their stalls. It has always been their place for food, drink, and rest. In their thoughts it is most safe and comfortable of all. Under the exalted excitement of the nerve-centres of the animal all their other instincts vanish.

I have a number of chickens which were hatched last spring and had never seen the snow until this winter. On a Friday evening one perched itself on an elevated portion of the hen-house. During the night a heavy snow fell. On the following Tuesday evening, my neighbor came in to tell me that there was a hen standing on top of my hen-house and that it had been standing there for four days. At least every time anybody looked out of the window the hen was seen standing in the same position, and they concluded she must have been standing there all this time. I became interested and at once went into the back yard and crawled on to the roof. I approached the hen; she paid not the slightest attention to my presence; she seemed perfectly unconscious to all surroundings. As I put out my hands toward her, she did not move, but after I seized her she at once began to squawk, even before I had said, "Right, right, you're all right now."

In looking from a high tower or precipice the feeling that comes over some people is cognate to hypnotism. Wonder, awe, and fear so utilize the vital forces that reasoning and self-control are temporarily gone. The many so-called suicides committed by jumping into Niagara Falls, or from high towers, are acts committed in the hypnotic state; at least I believe a great mistake is made in indiscriminately calling such acts suicide. It is a notable fact that all high towers have to be protected so that people cannot jump from them. The Washington Tower, the Fire Tower at London, the Eiffel Tower, the dome at the Capitol of Washington, and many others have had wire net-work or other apparatus put up to prevent persons from jumping from them. I think it is a grave injustice to call all such acts suicide.

It is a possible mistake to allow the word hypnotism to assume as broad an application as is now popular. In this sense every speaker, every preacher, is a hypnotist. Each suggests his good thoughts from the pulpit or the rostrum and endeavors thereby to influence his hearers. The successful jurist by rhetoric, oratory, earnestness, and gestures hypnotizes the jurymen until tears mark the result. Every business man and solicitor utilizes, to his utmost, suggestion for the sake of influencing his customers.

What I wish to point out in this article is that there need be no transferrence of a mysterious force from the operator to the subject to bring on hypnotic states, inasmuch as inanimate surroundings are adequate to produce a similar effect.

Considered in the line of the above hypothesis it is an easy matter to account for the changes that take place in so-called faith-cures. It is probably a fact that many deranged functions have been restored to a more normal action through an effect in the nerve-centres brought about by suggestion in the form of Christian science, hypnotism, or faith-cure.

We are fully aware that fright is often the exciting cause of deranging the nerve-centres to the extent of disturbing some important function. Fright has also been known to restore to normal action a disturbed function. In aphonia, which is of frequent occurrence in certain individuals suffering from nervous debility, the power of speech has often been restored by approaching the patient unobserved and suddenly making a loud sound close to the ear, causing fright. But recently I heard of what seemed to be a well authenticated case of a deaf girl being restored to hearing in a similar manner. A severe thunderbolt struck the house she was in, rendering several of the occupants partially insensible, immediately after which the little girl said, "Come, mother, let us go home, I can hear now."

This switching or transferrence of nerve-impulse may possess some value in scientific hands, but in no way does it fulfil the requirements of enfeebled or insufficient nerve-centres. The true end to be sought is a vigor and equilibrium of action in all the nerve-centres, from which all functions will receive a normal share of nerve-impulse for their performance; a condition which is hardly to be expected through suggestion or faith alone. A fair average of success in this direction is illustrated in Walter Scott's "Waverley," where the Scotchman tried to teach his mule to do without food. He gradually reduced the poor animal's feed until he ate but one straw a day, when he died, otherwise the experiment would have been a success.

In conclusion, I will repeat that hypnotism or suggestion is the diversion into other channels of those impulses that give rise to feeling, motion, and reason. They are turned aside from the performance of their normal functions to execute another kind of work.

903 Pullman Building.

He Probably Pays for Medical Services.—A clergyman of Columbus, O., recently returned a clerical pass which a railroad company sent him, with the following explanation: "I never use clerical tickets, because I know no reason why clergymen should have privileges not granted to the mechanics and laboring men, and because I am not satisfied that railways have any right to grant the favor to anybody."

A New Form of Medical Sweating.—The organizer of one of the many "personally conducted" trips to the Holy Land, has issued a circular in which he makes the munificent offer of a reduction of twenty-five per cent. to any medical man who will accompany the party and treat its members free of cost. An English journal estimates, from the cost of the excursion and the length of the trip, that this is equivalent to a salary of $10 a week.

Progress of Medical Science.

The Operative Treatment of Gastric Ulcer.—Dr. Küster not long ago recorded a case of ulcer of the stomach in which surgical interference was followed by recovery. He now reports a second case of gastric ulcer successfully treated by incision of the stomach, thermic cauterization, and gastro-enterostomy. The former case was reported to the last Congress of German Surgeons. The subject of the present record was an emaciated man, aged forty-two, who for six years had suffered from frequent attacks of pain in the stomach and of vomiting. In the spring of last year the vomited matter and also the stools were deeply stained with blood. The stomach for some months before the patient came under the author's notice had been much dilated. On June 27th the stomach was exposed by an incision made in the middle line of the abdominal wall above the navel. An ulcer could be felt in the posterior wall of the viscus near the pylorus. An incision having been made through the anterior wall of the much-dilated stomach, parallel with the greater curvature, the cut edges were widely separated, and the thermo-cautery applied to the surface of the ulcer, which was about the size of a one-cent piece. Communication was next established between the stomach and jejunum. The progress toward recovery was much disturbed by frequent distention of the stomach by abundant yellow fluid, for the removal of which it was found necessary to wash out the organ very frequently in the course of the first five days following that of the operation. Besides this hindrance, large accumulation of blood and serum in the external wound rendered it necessary to remove some of the external sutures and to separate the edges. The patient, when discharged at the end of six weeks, was free from pain in the stomach, and able to take both solid and fluid food without discomfort. Two months later he was still in good health, and had increased considerably in weight.

The Urine in Chronic Arsenical Poisoning.— Dr. Hills records the results of 260 analyses of urine for arsenic, representing 180 cases. Of these, in 135, or seventy-five per cent., arsenic was found; but it is not claimed that in all these cases there were symptoms of arsenical poisoning; in many cases, Hills says, that doubtless the presence of arsenic was a mere coincidence. He is convinced that there are sources of accidental poisoning which have hitherto escaped observation. The discovery of the coexistence of copper in one case—it was not looked for in others—suggests Paris green as one such source sometimes, and presumably in some article of food. He points out, however, that it is possible that in the free use of Paris green in the garden and field we have a hitherto unrecognized source of poisoning; the soil in many localities is, doubtless, impregnated with the poison. Another possible source is coal; and, if arsenic is a constituent of coal, there can be no doubt that it must be liberated during the process of combustion. The suggestion has also been made that illuminating gas might contain some arsenic, and Hills strongly recommends further investigation in both these directions as likely to lead to important results. The quantity of arsenic eliminated daily by the kidneys is very small, as a rule less than 0.01 milligr. per litre of urine; it is not surprising, therefore, that the time required for its elimination should be great; in several of his own cases about eighty days elapsed before the arsenic had completely disappeared from the urine. Among the more important complications of this form of poisoning is albuminuria, with hyperæmia of the kidney; his attention was not directed to this point in the early stages of his investigation, but in 70 cases a complete chemical and microscopical examination of the urine was made, with the result that in 23 there was no renal complication, while in 47 there was evidence of renal hyperæmia. Hills concludes from his own observation that when the system has absorbed such an amount of arsenic that the quantity eliminated with the urine daily is relatively large (0.03 to 0.05 milligr. per litre) there appear, sooner or later, evidences of renal hyperæmia, and that the kidneys are not apparently, as a rule, susceptible to arsenic, when the latter is present in the urine in quantities below 0.02 milligr. per litre. In the discussion which followed the reading of the paper, E. S. Wood confirmed the views of the author from his own experience in several important particulars, and gave two instances in which the hot air coming from the furnace and the coal-dust of the furnace were found to be highly charged with arsenic, a statement confirmed by the next speaker, Davenport, who instanced as other sources of arsenic-poisoning the ordinary silk coat-sleeve lining, the ordinary brown paper carpet lining, and the common black cambric furniture lining; in fact, according to him, the sources of arsenic were almost innumerable, and he wondered that poisoning was not more common. Putnam dealt with the subject from the clinical side, and threw out the suggestion that in paralysis from neuritis owing to this cause treatment by arsenic might be beneficial. Bolles narrated very fully the case of a child whose urine had almost without intermission during five years contained arsenic, notwithstanding the most strenuous efforts to remove him from every possible source of the poison. Considering the rarity of domestic poisoning by arsenic in this country at the present time, we cannot but feel that in the furnace, as the chief distinguishing feature in the home life of the two countries, a very real source of the danger has been found.—*The Boston Medical and Surgical Journal.*

Suture of Ruptured Uterus per Vaginam.— Dr. Cholmogoroff, in a bad case of rupture of the uterus, where the laceration was situated low down, succeeded in effecting suture from below (*The British Medical Journal*). The breech had presented; it was drawn down, then the after-coming head had to be perforated through the hard palate. Expression proved useless for expelling the placenta; the hand was introduced into the uterus and a transverse laceration was detected, four inches long, an inch above the external os. The placenta was found lying amid intestine, and was extracted. Cholmogoroff feared to perform laparotomy; the labor had not been conducted antiseptically, and he believed in Mikulicz's iodoform gauze tamponade. He washed out the peritoneal cavity by means of a long glass tube with a warm two per cent. solution of boracic acid. Then he steadied the cervix with four volsella forceps, and introduced sutures into the edges of the laceration. The serous coat was included. One end of the wound was left open, and the end of a long strip of iodoform gauze passed through it into the abdominal cavity. The opening was long enough to admit two fingers. The bleeding then ceased. The uterine cavity and vagina were packed with iodoform gauze, and the ends of the ten sutures wrapped in gauze. On the fourth day the tampons were removed, but the strip of gauze entering the peritoneal cavity was left alone; the vagina was again packed. The gauze was removed from the peritoneal cavity on the eighth day. On the tenth day there was a rigor, due to inflammation of the left breast, an abscess formed and gave trouble. The sutures were removed, and it was found that the laceration had united by first intention. Cholmogoroff considers this practice good surgery, as the laceration is closed and antisepsis insured by drainage. Suture of a uterine laceration is only practicable from the vaginal side when the rent lies below the contraction ring. This position is, however, the most frequent after labor.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, May 4, 1895.

THE USE OF OPIUM.

THE recent Report to Parliament of the Royal Opium Commission commending the use of the drug in India, while it may tell the truth, will, we fear, for a time, do a very great deal of harm. India gets a large part of her revenues from opium, hence its government is naturally suspected of having somewhat biassed views on the subject. In response to a demand from the Anti-Opium League, a Commission was appointed some time ago to take testimony on the matter and draw up a report. In the course of its labors, over seven hundred and twenty witnesses were examined by the Commission, including one hundred and fifty-two called at the desire of the Anti-Opium Society. Every care, we are told, was taken to obtain representative testimony, and the Commission record their conviction that the evidence forms sufficient trustworthy ground for the conclusions reached.

The report states that one hundred and sixty-one medical men were examined, and that their testimony was practically unanimous to the effect that "the temperate use of opium in India should be viewed in the same light as the temperate use of alcohol in England. Opium is harmful, harmless, or even beneficial, according to the measure and discretion with which it is used."

The natives of India, on the whole, are said to agree with the doctors. It is universally allowed that the excessive consumption of opium is an evil, though an evil of which the effects have been grossly exaggerated.

The report adds that opium is largely taken as a stimulant by those past middle age. They use it, in the striking phrase of one of the witnesses, "as a prop to a falling house." In the opinion of the great majority of native medical practitioners and representatives of large, influential classes, this employment of the drug is attended by beneficial results. Opium eaters of fifteen to twenty years' standing appeared before the Commission. They believed the habit had done them good. Their appearance and vigor satisfied the Commissioners, at all events, that it had done them no perceptible harm.

Opium is also used as an occasional stimulant in physical emergencies. It has been issued, by medical advice, to troops engaged in fighting and road-making among the mountains of Sikkim. It is taken occasionally by camel drivers who work in the extremes of heat and cold that prevail in the Rajputana Desert. Many consumers in the Punjab use the drug in the winter months only.

There can be, we presume, no disputing the conclusions above given so far as the Indian race is concerned. Even here, however, the question whether the race would not, on the whole, be better if no opium were used, is not answered.

So far as Caucasians are concerned we cannot too emphatically assert that the Commission's conclusions do not apply at all. The use of opium is a distinct evil. Its moderate use is impossible; there are practically no temperate opium users. The opium eater always wants more and continues to want more until he is physically and mentally a wreck.

MILK AND TYPHOID FEVER.

THE present epidemic of typhoid fever in Stamford, Conn., due to infected milk, is another strikingly corroborative demonstration of the value of careful examination into the relations of cause and effect in suspicious cases. The truth of this has been proved so often, especially in regard to milk-supply in its relations to the spread of the fever in given localities, that there is no doubt of its impressive vindication. While the history of the typhoid epidemic of Montclair, N. J., is still fresh in our minds, we find a repetition of parallel experiences, based on the investigations of the Stamford Health Officer. In both instances the milk-supply was traced to one source of infection. One milkman is seemingly accountable for all the damage done. Health Officer Hexamer, as soon as the fever assumed an epidemic form, instituted a system of inspection which promptly cleared up an apparent mystery and confirmed well-grounded apprehensions.

He marked on a map of Stamford, in red ink, the infected houses, and in black ink the routes of the milk dealers. In all but five cases, the infected houses were on the streets supplied by one milkman. Dr. C. A. Lindsley, Secretary of the State Board of Health, and Dr. Herbert E. Smith, of New Haven, were summoned to Stamford by Dr. Hexamer.

It was found that the milkman's barns were in the rear of his lot, and surrounded on all sides by dwellings and outbuildings. His tank for cooling milk was in the northwestern corner of a barn. This was fed by a pump drawing water from a well 12½ feet deep and filled with water to within 1½ foot of the surface. West of the pump were two outhouses, one 20 feet and the other 15 feet, each above the level of the bottom of the well. The slope of the land was toward the east, and the drainage from the outhouses led directly toward the pump. The ground was clay, covered with gravel, with surface soil above.

The well-water was examined by Dr. T. Mitchell Prudden, of this city, and found to be swarming with bacteria. Water taken from two wells to the west of that water-supply and one to the south were found to be contaminated, and the wells were ordered to be closed.

It is believed that the typhoid-fever germs were first brought to this neighborhood by the Italians in the em-

ploy of the New York, New Haven & Hartford Railroad.

During the past few weeks they have been at work in the section of the town in which the milkman's dairy is situated. There has been sickness among them, and the disease can be traced almost directly to their camp.

The cases under treatment are fortunately of a mild type, and it is believed that the epidemic is now virtually checked.

Dr. Hexamer, in an elaborate report on the subject, very properly recommends that a milk inspector be added to the Health Department. Indeed such an official should be connected with every health board in the country.

THE PUNISHMENT FOR SEXUAL CRIMES.

Ignoring the refinements of pornographic alienists, English law recognizes only three forms of sexual perversion—tribadism, sodomy, and bestiality. The first term is applied to sexual relations between women; sodomy is the name for the same kind of vice occurring in men. When the criminals are man and boy, it is called pæderasty; and so far as one can judge it is the discovery of this latter form of vice that has occasioned such an excitement in England. In old times, says Tidy, sodomy was in most countries punishable with death. The English law is now less severe, and the criminal is liable to penal servitude for life or for any term not less than ten years.

THE TREATMENT OF PNEUMONIA.

In an article on the treatment of pneumonia (*Therapeutic Gazette*) Dr. Hobart A. Hare asserts that in the early and hyperæmic stage, quinine and veratrum viride possess practical value. After exudation has taken place, the three sheet-anchors of treatment are, digitalis, strychnine, and belladonna. Of these three he thinks that strychnine is the only one which one can use alone with advantage. The digitalis nearly always fails to stimulate the vaso-motor system sufficiently, and the belladonna has to be added to regulate the blood-flow by its vascular action. "Often, when using digitalis in pneumonia, the finger upon the pulse shows it to be full, but soft and boggy, if such a term may be used; and while the regularity and slowness, as well as the volume, may indicate the full action of digitalis, the patient fails to receive benefit and may have a leaky skin. Under these circumstances, belladonna given in the dose of about five drops of the tincture every three or four hours, while the digitalis is given in ten-drop doses every six or eight hours, will produce marked improvement. The strychnine finds its great value as a whip to the entire system—as a whip which will pull the patient out of collapse or syncope, or overcome the peculiar torpor which is so dangerous a symptom in this disease, indicating, as it does, that the CO_2 is accumulating in the blood, or that the poison of the disease is obtunding the nerve-centres. Particularly are strychnine and belladonna useful about the time of crisis, when the rapid fall of temperature takes away the stimulating effect of the heat and produces collapse."

A case is cited in which hypodermic injections of gr. $\frac{1}{60}$ strychnine and gr. $\frac{1}{120}$ of atropia every fifteen minutes for three doses brought the patient out of a critical state.

This treatment of pneumonia by veratrum viride, digitalis, strychnia, and atropine, is a good deal in harmony with the so-called dosimetric treatment with digitaline, aconitine, and strychnia, a method that was much in vogue in the hospitals of New York for a few seasons, but which now we believe is not much practised. Dr. Hare seems to attach little importance to the hydrotherapeutic treatment which in some cases proved itself most efficient.

ANTI-ASPHYXIATION ASSOCIATION.

It so frequently happens that the news columns of the daily press contain accounts of deaths from illuminating gas under circumstances which scarcely admit of the usual theory of suicide, that we wonder no one has before this urged the necessity of a regular inspection of gas-burners in all hotels, lodging and boarding-houses.

The letter from a subscriber, printed under "Correspondence" in this issue of the Record, draws attention to a source of danger which surely should be investigated, and, if found to exist, receive correction.

News of the Week.

Death of Professor Karl Ludwig.—A cablegram announces the death, on April 27th, of Professor Karl Ludwig, the eminent physiologist, in Leipsic, Saxony, at the age of seventy-nine. Among the last words his friends heard him say were: "I am satisfied with my life's work and am glad to die." Karl Ludwig was born December 23, 1816, in Witzenhausen. He studied medicine in Marburg and Erlangen, and secured the degree of M.D. in 1839. He was elected Demonstrator of Anatomy in Marburg in 1841, and in 1846 was made Professor of Anatomy. He was called to the post of Professor of Anatomy and Physiology at Zurich in 1849, and in 1855 he became Professor of Physiology in Vienna, Austria. He left Vienna in 1865 to take charge of the Chair of Physiology in Leipsic, Saxony, which office he retained until his death. Professor Ludwig was conceded to be one of the foremost physiologists in the world, ranking with Claude Bernard. It is said that nearly half the physiology known is due to him and his pupils. He invented the kynographic method for the study of blood-pressure. Among his noted publications are "The Gas of the Blood," written in 1869; also "The Structural Conditions of the Heart, the Liver, the Kidneys, and other Internal Organs," and "The Secretion of the Kidneys."

A Bill making Insanity of five years' duration a legal ground for divorce was recently introduced into the Illinois State Legislature, but was promptly defeated.

An East-side Medical Society.—A large number of physicians in the lower part of the city have organized a new society to be known as the Eastern Medical Society. In its platform the society denounces organizations giving free aid to the poor without discrimination.

The Regulation of Medical Practice in Maine.—An act to regulate the Practice of Medicine and Surgery has been passed by the Maine Legislature. The bill received the approval and support of the Maine Academy of Medicine, and its passage was largely due to the character and influence of prominent members of the Academy. In the judgment of the *Journal of Medicine and Science*, the organ of the Academy, the bill is not an ideal one, but is a better one than the first passed by most States and Territories. The passage of this law alone is a most successful result of organized action on the part of medical men; and the Maine Academy may well be proud of such marked success so early in its career.—*Boston Medical and Surgical Journal.*

The Cycle as an Ambulance Carriage.—A new ambulance carriage has been invented by Dr. Hönig, of Berlin. It is not drawn by horses or men in the ordinary way, but is propelled by cyclists, and consists of a kind of litter resting on a frame with five wheels, three in front in the form of an ordinary tricycle, and two at the back. The drivers accordingly sit one at each end of the litter, which is covered by a removable roof with little windows and a pneumatic bell, so that the patient can communicate with the drivers. Beneath the litter are boxes for dressing materials, instruments for first aid, etc. Dr. Hönig suggests that his invention would be useful in small towns for which a horse ambulance is too expensive. It brings the surgeon and his assistant very quickly to the scene of an accident, and enables them to remove the patient to the hospital without loss of time. The general opinion here is that the new system will require a greater proficiency in the art of cycling than the majority of medical men possess. The carriage was shown in the drill-ground of the fire brigade to surgeons attached to hospitals and the police, as well as to officers of police and the fire brigades, and to other gentlemen connected with the ambulance service.—*Lancet.*

"Kissing the Book."—The Legislature of Pennsylvania has decreed that the oath on the Bible shall be dispensed with. The Governor of the State has indicated that he will approve of the enactments to that end.

A New Morgue for Paris.—It is announced that Paris is to have a new morgue. The historical building will still remain, but a vaster construction will be devoted to the frozen museum of bodies that are now hidden away in drawers. Dr. Bertillon is of opinion that the possibility of identifying corpses ought to be extended over three months. The site of the new morgue is not yet settled.

Medical Legislation in Kansas.—The Kansas Medical Practice Bill was defeated chiefly through the influence of the Populists. In the House, according to the *Kansas Medical Journal*, Mr. Winters, a Populist member, said: "We Western people can't support your plug-hat doctors. We've got a lot of old women who are better than any of them."

Portraits of Medical Men.—The meetings of the American Medical Association have of late been attended with a generous display of pictures of medical men in the daily prints. To those who think this is highly improper the following note from *The Provincial Medical Journal* will prove a comfort. The *Journal* says: "We must confess we have not very much sympathy with the *ultra purism* which condemns such a publication as the issue of *St. Paul's* [an illustrated popular journal]. The lay public are familiar with the features of our leading public men—our statesmen, our writers, our lawyers—through the lay press; why should they not also be made familiar with the features of those who are doing better work? We may take it as an axiom that when a man has arrived at the stage that his portrait is selected for publication in such a paper as *St. Paul's*, an advertisement is not needed by him."

Meetings of State and National Medical Societies in May.—The following medical societies hold their annual meetings during the present month: Missouri State Medical Association, May 21, at Hannibal, Mo. National Association of Railway Surgeons, May 1–3, at Chicago, Ill. Nebraska State Medical Society, May 21, 22, 23, at Grand Island, Neb. New Hampshire Medical Society, May 30 and 31, at Concord, N. H. American Pediatric Society, May 27–29, at Hot Springs, Va. Arkansas Medical Society, May 1, at Little Rock, Ark. Army and Navy Medical Association, May 28, at Decatur, Ill. Association of American Physicians, May 28–31, at Washington, D. C. Association of Military Surgeons of the United States, May 21–23, at Buffalo, N. Y. American Gynecological Society, May 28, at Washington, D. C. American Laryngological Association, May 28, at Rochester, N. Y. American Medical Association, May 7, at Baltimore, Md. Medical Society of the State of North Carolina, May 14–16, at Goldsboro, N. C. Medical Society of the State of Pennsylvania, May 21, at Chambersburg, Pa. American Academy of Medicine, May 4–6, at Baltimore, Md. American Association of Genito-urinary Surgeons, May 28–31, at Niagara Falls, N. Y. Louisiana State Medical Society, May 7, at New Orleans. Ohio State Medical Society, May 15–17, at Columbus, O. Washington State Medical Society at Seattle. Connecticut State Medical Society on May 1, at New Haven.

Society of the German Poliklinik.—The first scientific meeting of the staff of the German Poliklinik was held in their building, 78 Seventh Street, April 16th, Dr. F. N. Lilienthal, acting chairman. Dr. Aronson presented a case of leukæmia; Dr. Freudenthal a case of bulbar paralysis; Dr. Leviseur read a paper on "Mycosis fungoides;" Dr. S. Fischer demonstrated a case of secondary glaucoma with iritis serosa and also dacryæcystoblenorrhœa occurring in the practice of Dr. Henry S. Oppenheimer; Dr. Romm demonstrated a case of paralysis agitans; Dr. L. Fischer demonstrated a new aseptic antitoxine syringe made entirely of glass

with an asbestos fitting; Dr. C. Beck demonstrated a new pocket sterilizer.

The Health Department of the City of New York has passed resolutions to the effect that any inspector or medical officer acting under the board who, when brought officially into contact with a case of infectious disease, interferes directly or indirectly with the attending physician's treatment, or who undertakes medical attendance in a family whose acquaintance he has made in the lines of his official duties, shall be dismissed from the service, unless he has been specifically instructed to perform the acts in question by the board or by a chief of division; also that the sanitary superintendent shall instruct all the medical sanitary inspectors anew as to their specific duties in respect to persons sick with infections disease. At a meeting of the New York County Medical Society, April 21st, a vote of thanks was adopted to the Board of Health for their action in this matter.

"**Medicine**" is the title of a new monthly journal, edited by Dr. Harold N. Moyer and published in Detroit by George S. Davis.

A Hahnemannian Hospital for the Insane is desired by twenty thousand persons of Pennsylvania, who have petitioned the Legislature to that effect.

An Omitted Credit.—We take pleasure in giving credit to the *Medical News* for an item regarding the New York Board of Medical Examiners which appeared in our columns on March 23d. The omission at the time was entirely accidental and unintentional. It is the intention of the MEDICAL RECORD to give full credit to the journals from which it quotes.

The Lepers of Tracadie.—The report of the Dominion Agricultural Department, which has just been issued, states that there are now 21 patients in the lazaretto at Tracadie, New Brunswick. There are 12 males and 9 females in the hospital, 10 of the patients being in the third or final stage. Their ages run from eight to eighty-one years. Only one patient was admitted during the year. There are three lepers in the settlement outside of the lazaretto, but these will be taken in as soon as the new hospital, now in course of construction, is completed.

The Societies for First Aid to the Injured in this city have formed an Alumni Association with E. F. Thurston as President, and Dr. E. L. Partridge as Medical Director, and it has an apartment in the United Charities Building. The association is composed of some students in the course of instruction given by the Society for First Aid to the Injured who have passed examination and received diplomas. President Thurston disclaims any intention of the alumni to trespass on the profits or prerogatives of physicians. All that First Aid students aim at is to be able to render service in emergencies, and this has been done in many cases when "the ambulance was summoned."

Medical Legislation in Minnesota.—The Legislature just adjourned has dealt generously with the medical profession of this State. The Medical Department of the State University received $40,000 for a laboratory building, making a total of $150,000 appropriated for buildings alone in a period of four years. The medical law was likewise amended to require of all graduates of later date than 1898 "attendance upon four courses of medical lectures, in different years, of not less than six months' duration each." The provisions of this amendment will therefore exclude from practice in Minnesota alumni of all schools matriculating students the coming session under the provisions of the three years' curricula. The minimum provisions of the old act required attendance upon "three courses of six months' duration each."

The Cholera is raging again this year at Mecca, and the Sultan has been asked to stop the pilgrimage from India. He has refused to do so owing to the fear of offending the religious prejudices of his subjects. At Kamaran Island, in the Red Sea, where the quarantine station for the Indian pilgrims is situated, there were detained some weeks ago over two thousand persons, among whom there were about twenty deaths a day from cholera. The lazaretto is reported to be in an indescribably filthy condition and the continued spread of the disease among its inmates is attributed to this cause. The last great epidemic in Mecca was during the pilgrimage of 1891, when between eleven thousand and twelve thousand deaths occurred.

The Office of Coroner.—Assembly Bill No. 2123, embodying the theory of the last Constitutional Convention in relation to the abolition of the office of coroner and placing this most important function on a more desirable and dignified basis is now being considered by the Legislature. This bill was drawn by a joint committee of the State Bar Association and the State Medical Society. Under its provisions the District Attorney in each county appoints, for every 40,000 inhabitants, a medico-legal officer, who is charged with the medical aspect of all cases of suspicious deaths occurring in his district. The bill is so drawn as not to affect coroners or coroners' physicians now in office, they continuing on until the term of office for which they have been elected shall have expired.

A German Degree for a Woman.—Miss Grace Chisholm, an Englishwoman, has the honor, we believe, of being the first of her sex to obtain the degree of Ph.D. from a German university, or at least from the University of Göttingen. This the young lady has just done with the express consent and approval of the Prussian Minister of Education, and therefore of the Emperor William II. The latter has hitherto had notions as antiquated as those of Sir Dyce Duckworth concerning the higher education of women, and his consent to the conferring of the doctorate upon Miss Chisholm would seem to imply that he has determined to yield with good grace to the inevitable.

Trouble Getting Surgeons in the Navy.—Places in the medical corps of the navy seem to be no longer in demand, and the greatest difficulty is now experienced in getting young physicians to enter the service. The trouble seems to lie in the dissatisfaction which associations with naval cadets, clerks, and junior officers in the steerage causes the young surgeons, who believe that men of their years and learning should be treated with greater consideration. Physicians, on entering the

navy, have the relative rank of ensigns, and on all large ships are berthed for their first cruise in the steerage. Here they have little opportunity of association with men of their age, and must mess with the youngsters and sleep alongside them in hammocks. Surgeon-General Tryon has endeavored to have the new physicians placed in ward-room messes, but Admiral Ramsay is a stickler for regulations, and insists that all officers, whether of staff or line, shall be messed according to their rank. There are now nine vacancies in the grade of assistant surgeon, and two more will be created this month. Seven of these vacancies have existed for upward of a year, and there seems to be little prospect of filling them in the next few months. While the examination and requirements for admission are exceedingly rigorous, the fact that there are few or no applications indicates that there is no disposition on the part of young physicians to enter the navy.

Addition to Brooklyn Naval Hospital.—Plans have been completed for the addition to the Naval Hospital at Brooklyn. There is available for this work about sixty-nine thousand dollars. The plans contemplate a substantial structure in the form of a wing to the present edifice. The addition will result in enlarged quarters for the sick. There will also be a completely equipped operating-room.

Beware of the Tongue Sandwich.—Dr. C. W. Stiles, of the Agricultural Department, Washington, has written an article "On the Rarity of Tenia Solium in America." Dr. Stiles describes the different kinds of tenia. The tongue of the beef is a favorite place for these parasites to collect, and those who are fond of beef-tongue sandwiches run considerable risk.

The German Otological Society meets this year in Jena, June 1st and 2d.

Telephone Rates' Bill in the New York Legislature.—The physicians of New York, to whom the use of the telephone has grown to the height of a necessity, have exhibited unwonted interest in this year's campaign against existing extortionate rates. The bill against the companies, as originally introduced, fixed the rates at $78 and $66 respectively. These rates have since been increased to $125 and $85 respectively. Moreover, a six months' continuance of the old high rates is permitted, and the companies cannot be bound to follow the new schedule if they can show that they are not remunerative. The companies are very powerful at Albany, and have been able, year after year, to thwart the efforts of physicians and others to lower the tariff. Medical men in other States besides New York will be interested to follow the progress of this fight with this grasping monopoly.—*Journal of the American Medical Association.*

Another Jubilee Hospital.—The medical profession of Vienna proposes to commemorate the fiftieth year of the reign of the Emperor Francis Joseph of Austria by the foundation of a hospital for children, with a capacity of one thousand beds.

A Tax on Doctors.—The doctors of North Carolina must hereafter pay an annual tax of $10 into the State Treasury for the privilege of practising medicine! That is the edict of the mongrel Legislature which has been in session in Raleigh, and which has attracted the attention of the whole country by the many strange things they have done. But can an evil tree bring forth good fruit? Verily, no.—*North Carolina Medical Journal.*

Obituary Notes.—Dr. Carl Thiersch died on April 28th, at his home in Leipsic, aged seventy-three. He was born in Munich on April 20, 1822, and studied medicine there and in Berlin, Vienna, and Paris. He was made Professor of Surgery at Erlangen in 1854, and was called to the same chair in Leipsic in 1867. During the Franco-German War he served as chief surgeon of the Twelfth Army Corps. His name is associated with the method of skin-grafting by means of broad strips of skin.—Dr. J. P. Wall, of Tampa, Fla., died on April 18th, while reading a paper before the Florida Medical Association in annual session at Gainesville.—Dr. Joseph L. Wade, health officer of Irvington, N. J., died on April 20th, aged sixty-six.—Dr. M. H. Burton, of Troy, N. Y., died on April 28th, at Bay Shore, L. I. He was a graduate of the Albany Medical College, and was President of the Alumni Association of that college. He was for sixteen years Health Officer of Troy. He was a delegate to the Medical Conference at Berlin.—Dr. Peter H. Madden, of Woonsocket, R. I., aged sixty-seven, died April 29th. He was educated in Ireland, Paris, and Belgium, and had practised in Woonsocket since 1860.

Private Hospital for Contagious Diseases.—The subscriptions to this proposed hospital now amount to over sixty thousand dollars. It is desired to obtain $75,000 before beginning work on the buildings.

The Samaritan Hospital for Women, Montreal.—A new hospital for women, with the above name, was opened by Her Excellency the Countess of Aberdeen, wife of the Governor-General of Canada, on January 17, 1895. It is the only special hospital for diseases of women in Montreal, and will be moulded on the pattern of the Women's Hospital of the State of New York in this city. It is managed by a board of thirty ladies, assisted by an advisory board of three laymen and three physicians. The staff consists of Sir James Grant, M.D., consulting physician; Dr. Wm. H. Hingston, consulting surgeon; Dr. A. Lapthorn Smith, surgeon-in chief; Dr. H. Lionel Reddy, surgeon; Dr. S. F. Wilson, assistant surgeon and registrar; Dr. Sylvester, assistant surgeon, and Dr. Letellier de St. Just, assistant surgeon.

The Third International Congress of Dermatology will be held in London, on August 4 to 8, 1896. The president of the Congress will be Mr. Jonathan Hutchinson; treasurer, Mr. Malcolm Morris; secretary-general, Dr. J. J. Pringle; secretary for the United States, Dr. G. T. Jackson; vice-presidents for the United States, Drs. Bulkley, Keyes, and Fox, of New York; Duhring, of Philadelphia; White, of Boston, and J. Nevins Hyde, of Chicago; vice-presidents for Canada, Drs. Shepherd, of Montreal, and Graham, of Toronto.

The Medical Association of Georgia.—At the last annual meeting of this Association, held in Savannah on April 17th to 19th, Dr. F. M. Ridley, of La Grange, was elected president, Drs. W. H. Doughty, of Augusta,

and M. L. Boyd, of Savannah, vice-presidents, and Dr. R. N. Taylor, of Griffin, secretary. The next meeting will be held in Augusta. At the close of the meeting an ophthalmological section of the Association was organized and Dr. J. L. Hiers was elected chairman, and Dr. W. F. Aiken secretary.

The Charcot Monument Fund.—The total amount of the subscriptions to this fund from this country and Canada is now $813.

Improvements at Quarantine.—A bacteriological laboratory has been fitted up in the executive building at the quarantine station of this port, and will soon be placed in charge of a well qualified bacteriologist. In order to permit vessels to come up to their piers at night, the health officer, Dr. Doty, has consented to pass vessels after nightfall. The night inspection of passengers will be accomplished by aid of a 300-candle-power electric light, which will be carried in the health officer's boat and will be attached to the electric light system of the vessel to be examined. The light consists of a single incandescent bulb.

Four Years' Course in Homœopathy.—Dr. F. Mortimer Lawrence, of Philadelphia, writes: "In your enumeration of the medical schools of the United States which absolutely require a four year course for graduation you have omitted the name of the Hahnemann Medical College of Philadelphia, which two years ago, considerably in advance of several of the schools mentioned in your paragraph, announced its lengthened curriculum."

The Case of Landry's Paralysis.—Dr. Beverly Robinson writes: "Would you kindly direct attention in the next issue of the MEDICAL RECORD to the fact that an error has been made in the report of the autopsy of the case of Landry's paralysis printed in the MEDICAL RECORD of April 27, 1895. The report of the brain examination under autopsy of Landry's paralysis properly belongs in great part to the case of brain tumor printed immediately afterward."

American Association of Medical Editors.—The annual dinner of the American Association of Medical Editors will take place Monday, May 6, 1895, at the Equitable Building (ninth floor), Calvert and Fayette Streets, Baltimore. A business meeting will be held at 6.30 P.M., at the same place. Members may bring guests upon purchase of tickets for them. Banquet tickets, $5 each, can be obtained from William B. Canfield, M.D., Secretary, 1010 North Charles Street, Baltimore, Md.

The American Medical Association.—The forty-sixth annual meeting of the Association will be held in Baltimore on May 7, 8, 9, and 10, 1895. The question of the amendments to the constitution and by-laws, which was laid over from the meetings of 1893 and 1894, will be resumed at this session and probably settled permanently. The addresses at the general sessions will be as follows: Presidential address, by Dr. Donald Maclean, of Detroit; address on General Medicine, by Dr. William E. Quine, of Chicago; on General Surgery, by Dr. C. A. Wheaton, of St. Paul; on State Medicine, by Dr. H. D. Holton, of Brattleboro. The chairman of the Committee of Arrangements is Dr. J. J. Chisolm. The usual reduction of one and one-third fares for the round trip will be allowed to members by most of the railroads. On the fourth day of the meeting there will be an excursion to Gettysburg by special train, the fare being set at $1 per passenger, provided one hundred and fifty persons will take the trip. Notice of intention to make this excursion should be given at the registration office on the first day of the session. Dr. Charles Jacobs, of Brussels, will be the guest of the gynecological section, and, if a suitable subject can be found, will perform his operation of vaginal total extirpation of the uterus and appendages before the members of the section.

The Faculty of the Northwestern University Medical School, of Chicago, has received from Zurich, Switzerland, the acceptance by Winfield Scott Hall, Ph.D., of the Davis Professorship of Physiology. Dr. Hall graduated as a Bachelor of Science in the College of Liberal Arts of the Northwestern University in 1887, and in the Northwestern University Medical School in 1890.

Vaccination and the Referendum.—Obligatory vaccination is to cease in the Canton of Berne, Switzerland. An election just held showed that the anti-vaccinists cast 26,238 votes against 24,543 by their opponents.—*Journal of the American Medical Association.*

Twenty-five Per Cent. of the Johns Hopkins Medical School students are now women.

A New Idea for Medical Societies.—A curious innovation in society work has been introduced by the York Medical Society. Dr. Baxter Tyrie, the President, offered, a short time ago, a prize for the best impromptu speech, for competition among the members. We learn that about twenty members essayed their chance in this novel undertaking, and the judges awarded the prize to Mr. Vaughan Bateson, the son of a local solicitor. There is no doubt much room for improvement in the oratory at medical societies, but whether this desirable result will be obtained by the system of awarding a prize to the best speaker is a matter which does not call for serious discussion.—*Medical Press.*

A New Epidemic in Berlin.—Aphthous fever, an affection identical with bovine, foot-and-mouth disease, has been for some years constantly present in several places in the neighborhood of Berlin. This year it has invaded the city, and, although for the present only a part of Berlin is infected, the epidemic will undoubtedly spread over the whole town if no preventive measures are taken.

The Helmholtz Monument.—A monument will be erected in Berlin in honor of the late Professor Helmholtz.

An Aid to Prescription Writing.—*Doctor* (to fair patient): Put out your tongue. (Meanwhile he writes out a prescription.) There, that will do.—*Miss Chatterbox:* But, doctor, you did not even look at my tongue.—*Doctor:* No, I only wanted you to keep quiet while I wrote the prescription.—*Geillustreed Stuiversblad.*

Examination by Proxy.—The *Medical Standard* some years ago discussing medical Paris said that the old

Paris school of medicine never entertained a queerer character than that student who earned a livelihood by passing students' examinations for them. His imitation of voices was so perfect that intimate relatives were often deceived. Some diplomas granted to Americans just about this period possibly owed their origin to this skill, since these students studied other phases of Paris life than medicine. The State examinations of New York have repeated this phase of medical history. Two men have been detected acting as proxies in an examination. The students under whose names they posed have been rejected, and are to be placed on a blacklist as guilty of unprofessional conduct.

Recipes for Professorships.—Dr. Abraham Jacobi gives in a recent address the following recipes for becoming a college professor: "To be rich, well connected, and have relatives among hospital and college trustees is a very necessary mental equipment. To have a friend who is wealthy and endows a chair for you. In Germany be a son-in-law of a leading professor. A German privatdocent died lately at the ripe age of seventy-four, who proved incapacity for advancement by refusing to marry the daughter of the full chair. Write a text-book while you are young and fresh. There are so many that you can extract half a dozen and make the seventh with the aid of very little brains and much more *a posteriori*. Operate on two alleged lacerations daily, and let no more than fifty per cent. die of septicæmia. Prove that the best place for ovaries is in a jar."

This is a rather pessimistic view of the matter. In medical colleges of repute, a man must have a more than ordinary capacity and more than average educational equipment in order to secure a professorship. There is, however, as the *Medical Standard* says, one recipe for a professorship which is peculiarly American. This is to take $10, and start a medical college. But in New York and a few other States this is not possible, on account of the legal provisions regarding the incorporation of medical colleges.

The Results of the New York Medical Examination Law.—From the report of the Examination Department of the University of the State of New York we learn the following: An analysis of the results of the licensing examinations since September 1, 1891, shows: That 8.9 per cent. of the old-school candidates were rejected in 1892, 7.4 per cent. in 1893, and 20.2 per cent. in 1894; that 25 per cent. of the homœopathic candidates were rejected in 1892, 9.5 per cent. in 1893, and 13.7 per cent. in 1894; that 50 per cent. of the eclectic candidates were rejected in 1892, 28.5 per cent. in 1893, and 50 per cent. in 1894. During the three years, 56, 267, and 390 old-school candidates have been examined; 8, 21, and 51 homœopaths; and 4, 7, and 4 eclectics, making a total of 808, of which number 121, or 15 per cent., were rejected. This result is remarkable when we consider that admission to the licensing examinations presupposes the preliminary education required by statute and graduation with the degree of bachelor or doctor of medicine from a registered medical school. It speaks well for New York State medical schools that of the 445 candidates examined during the year ending July 31, 1894, 291 were graduates of New York medical schools, and 154 of schools of other States and countries, and that of the 88 candidates rejected at these examinations, 42 were graduates of New York medical schools, and 46 of schools of other States and countries.

An Anatomical Curiosity.—Dr. J. W. Ogle has recorded in the twenty-ninth volume of the *Journal of Anatomy and Physiology* an interesting example in which one of the roots of the left hypoglossal nerve passed through the left vertebral artery within the skull. An excellent drawing is reproduced, but the specimen itself was not preserved. We had almost thought, with Dr. Ogle, that the observation might have been a unique one, for although nerves passing through bones in early development (as, for instance, one of the supra-clavicular nerves passing through the clavicle) are well recognized, nerves passing through blood-vessels, especially arteries, are very rare. Instances are known of the internal anterior thoracic nerve passing through the axillary vein, and of the nerves at the bend of the elbow passing through one of the veins at that point; and the nerves passing into the thorax occasionally obtain a passage through the large venous trunks. It is therefore very remarkable that the only other instance of the passage of a nerve through an artery that we can find recorded is by Otto, who mentions a wax model in the anatomical museum of the Joseph-Academie in Vienna, where the hypoglossal nerve also ran through the vertebral artery. The same nerve and the same artery are involved, and it is very curious that such an anomalous development should apparently be thus limited.—*Lancet.*

The Mayor of Berlin on Loeffler's Bacillus.—In America when diphtheria is prevalent the bacteriological examination of suspected cases is made in municipal laboratories free of charge. The medical club of the Luisenstadt quarter accordingly asked the municipality to follow the example of America, and to make similar arrangements in Berlin. In the name of the town council the mayor answered that there was no need for this examination, as it was not yet proved that Loeffler's bacillus is really the sole cause of diphtheria. In the *Medical Reform* a medical man asks, ironically, if the mayor would be acknowledged as an authority on bacteriological questions, and, if not, on whose advice it was that he formed his opinion on the etiology of diphtheria. The other medical journals join in blaming the mayor for his peremptory and not over-polite answer. The question will now be taken up by the "Medical Stores," an establishment similar to the Army and Navy Stores, where the members of the profession can obtain medical articles at lower prices than in the ordinary shops. The directors of these stores now undertake general bacteriological examinations. Practitioners who desire to have their cases investigated procure from the stores pieces of sterilized cotton-wool packed in small sterilized glasses. A bit of the cotton-wool is to be pressed on the suspected membranes, then put back into the glass, and sent in a small box to the laboratory of the stores, where the examination is performed by a specially appointed bacteriologist. The practitioner receives an answer on the following day.

Reviews and Notices.

On Digestive Proteolysis. Being the Cartwright Lectures for 1894. By R. H. Chittenden, Ph.D., Professor of Physiological Chemistry in Yale University. New Haven: Tuttle, Morehouse & Taylor. 8vo, pp. 137.

Our readers will be glad to learn that the interesting and valuable lectures of Professor Chittenden, which have appeared in the Record of last year, have been collected and published in a single volume.

Treating of a subject of the greatest importance to the practitioner and scientist, it will doubtless find a place for itself in the library of every progressive student.

The Practice of Medicine. By William C. Goodno, M.D., Professor of the Practice of Medicine in the Hahnemann Medical College, Philadelphia. With Selections on Diseases of the Nervous System by Clarence Bartlett, Lecturer on Nervous Mental Diseases, Hahnemann Medical College, Philadelphia, Volume I. Specific Infectious Diseases of the Nervous System. 8vo, pp. 961. Philadelphia: Hahnemann Press. 1894.

This work, written for homœopathic practitioners, may be considered a representative of its class in respect to the manner and dosage of the remedies prescribed, although there is infused in it a judiciously conservative element regarding the therapeutics of the "old and dominant school." Indeed it impresses the reader with the fact that the triturations are often tributary and supplementary to the ordinary remedies employed by the regulars. Alimentation and stimulation have leading places, while suitable reliance is placed in times of great emergency upon indications which govern the therapeutics of the old school. The clinical phenomena of disease are well presented, the influences of bacteriology are consistently acknowledged, and the history of the different affections is well epitomized. It can scarcely be questioned from the homœopathic stand-point that the work is fully up to the times and shows a tendency to approach that common line of agreement which is based upon a broader principle than the upholding of a sect or the fighting for a dogma.

Fibroid Diseases of the Lung, including Fibroid Phthisis. By Sir Andrew Clark, M.D., W. J. Hadley, M.D., and Arnold Chaplin, M.D. With Tables and Eight Plates in Colors. Pp. 199. London: Charles Griffin & Co. (Limited). 1894.

The volume before us represents an enormous amount of clinical experience and literary investigation, and covers a subject of much practical importance. The discovery of the tubercle bacillus has simplified our conceptions of pulmonary phthisis, but it has had an overshadowing influence also in the current views of pathology. Most physicians have been content to believe that all phthisis is primarily and essentially a tubercular process.

The present authors have succeeded in showing that this is not the case. There are three forms of the phthisical affections, viz.: Tubercular phthisis, tuberculo-fibroid disease, and fibroid phthisis. In the first type the bacillus is primarily and chiefly at fault; in the second, the tubercular process is associated with a chronic fibroid induration; in the third type the tubercle bacillus is not found at all, and the disease is essentially a cirrhosis of the lungs. Fibroid phthisis, as thus defined, is extremely rare, for only forty-five cases are collected; tuberculo-fibroid disease is more common, but is much rarer than the pure tubercular disease. The work gives a full description of fibroid and tubercular fibroid phthisis, but we must refer our readers to it for details. Many illustrations add to the value of the book, which will occupy a permanent place in medical literature.

The Physician's Vade Mecum. Being a Hand-book of Medical and Surgical Reference, with the Usual Information and Tables. By Sebastian J. Wimmer, M.A., M.D., author of "Tables and Notes on Human Osteology," of "Memoranda and Tables of Human Anatomy;" Member of the Alumni Association of the New York College of Physicians and Surgeons, Metropolitan Medical Society, New York Press Club, etc. With additions by Frank S. Parsons, M.D., Editor of the *Philadelphia Times and Register*; Member of the American Medical Association, Massachusetts Medical Society; formerly Lecturer on Diseases of Children, College of Physicians and Surgeons, Boston, 1889–1892, etc. Philadelphia: The Medical Publishing Company, 718 Betz Building. 1894.

Narrow in size of page, broad in scope of subjects touched upon, thick with prescriptions and pointers, long drawn out as to its not faultless English, French, and German "interpreter"—compared with the distance it would carry one. Thin paper, small type, full index. Without the latter the patient would be over his need for the hint, before the doctor found it in the mass of matter.

Edwards's Hygiene, with Anatomy and Physiology. Being an Amplification of Edwards's "Catechism of Hygiene." By Joseph F. Edwards, A.M., M.D., Member of State Board of Health of Pennsylvania, etc. Intended for Schools and General Reading. 8vo, pp. 435. New York: Edward P. Slevin.

This is a very curious book, and is so bewilderingly unique that the general reader and primary scholar, for whom it is intended, deserves to have considerable commiseration in advance. The plan is, fortunately, original with the author, and we trust that it is sufficiently guarded by restrictions to prevent any other ambitious instructors from imitating it. We do not criticise the statements concerning hygienic principles, but the manner in which they are presented and illustrated.

The Annual Report of the Homœopathic Hospital at Middletown, N. Y., is a very elaborate one, and in its line is a notable addition to the literature of the treatment of insanity. The percentage of cures is, however, no better than by the less specific methods adopted by other asylums.

Suggestions to Hospital and Asylum Visitors. By John S. Billings, M.D., and Henry M. Hurd, M.D. With Introduction by S. Weir Mitchell. 12mo, pp. 48. Philadelphia: J. B. Lippincott Co. 1895.

This little book contains in very convenient form such practical suggestions as may serve lay visitors of hospitals and asylums. All the points are well taken and intelligently presented.

Principles of Surgery and Surgical Pathology. General Rules Governing Operations and the Application of Dressings. By Dr. Hermann Tillman, Professor in the University of Leipzig. Translated from the Third German Edition by John Rogers, M.D., and Benjamin Tilton, both of New York. Edited by Lewis A. Stimson, M.D., Professor of Surgery in the University of the City of New York. With 441 Illustrations. New York: D. Appleton & Co. 1894.

Surgical pathology is now universally recognized as the true basis of surgical practice. The volume before us is an excellent epitome of the most recent views at present current in Germany concerning the various morbid processes that come within the scope of the surgeon. The German school of surgery, and more parti-

cularly surgical pathology, is not so distinctive and peculiar as to give an undue bias to the American student, willing to be guided by its precepts and tenets. In fact modern surgery is truly international in its essential principles. The present work will commend itself to the attention more particularly of the student class. The translation has been well done, the illustrations are fairly well executed, and most of them are new.

Transactions of the New Hampshire Medical Society at the One Hundred and Third Anniversary, held at Concord, June 18 and 19, 1894.

This volume contains the usual number of papers, together with the report of the proceedings at the annual meeting of the Society. An interesting article is one by Dr. Conn on the "Sanitary Condition of Mexico."

Degeneration. By Max Nordau. Translated from the Second Edition of the German work. New York: D. Appleton & Company. 1895.

This is a treatise on degeneration and the degenerates written by one who, to take his own highly drawn presentation of the symptomatology of the affection as a guide, must be judged as possibly himself a sufferer from a mild form of the *fin-de-siècle* disease. The author is a follower of Lombroso, who goes a step farther than his master, and applies his touchstone of degeneracy to the founders of various schools in art and literature in vogue at the present day, and finds that they and their followers are as surely degenerates as the criminals, prostitutes, anarchists, and other disturbers of society, who have been the favorite subjects of Lombroso's study. Eccentricity, genius, or pseudo-genius, and self-adulation, are the hall-marks of the leaders among the æsthetic degenerates, while servile imitation, lack of originality, love of novelty, and complacent self and mutual admiration characterize their followers. Among those whom Nordan studies as types of the non-criminal degenerates (not criminal possibly because the occasion of crime has chanced to be wanting) are Rossetti, Swinburne, Wagner, Tolstoi, Zola, Nietzsche, Ibsen, Verlaine, and Mellarmé. The freedom with which the author analyzes the psychic symptoms of living writers and establishes, to his own satisfaction at least, the diagnosis of their degeneracy and mental unsoundness must be not altogether agreeable to the subjects of his study. This makes the book all the more interesting, however, to the multitude, who, not being named specifically, are at liberty to consider themselves sane in most respects, especially in their judgments concerning their fellows. The book is indeed an absorbingly entertaining one, and contains a vast deal of food for thought. The author knows his subject thoroughly, knows what he wants to say and how to say it, and whether or no we agree with him, we are forced to confess that his warnings are not to be despised, that the *fin-de-siècle* disease is a reality, and that there is danger to the race if it spread to the *bourgeoisie*, to the "common people," in whose keeping is the fortune of humanity. But there is little fear that it will spread, and indeed we are not sure that a little leaven of "degeneracy" is not salutary in this intensely practical age.

Therapeutic Suggestion in Psychopathia Sexualis, with Especial Reference to Contrary Sexual Instinct. By Dr. A. von Schrenck-Notzing, Practising Physician in Munich. Authorized Translation from the German, by Charles Gilbert Chaddock, M.D., Professor of Diseases of the Nervous System, Marion-Sims College of Medicine, etc. Philadelphia: The F. A. Davis Company. 1895.

This is a book on the same line as that of von Krafft-Ebing, the special object being to show the effect of hypnotism and suggestive therapeutics in the treatment of perverted sexual instinct. We cannot see that it will serve any useful purpose, or rather the good that may possibly come from it will, we believe, be more than counterbalanced by the harm which will come to the young from a perusal of the many cases of sexual perversion recounted, often by the victims themselves, in revolting and unnecessary detail. Furthermore, we would energetically protest against the doctrine, which the author boldly avows, of practically unrestrained fornication. The question of morality aside, we fail to see that an onanist is much better off for becoming a frequenter of brothels and a victim of venereal disease in the hope, which is by no means always realized, of curing himself of his original vice.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, April 18, 1895.

Joseph D. Bryant, M.D., President in the Chair.

Doctors and the Presidency of the Board of Health.—Dr. H. D. Chapin offered a resolution, supported by an argument, endorsing the bill before the Legislature to remove the disqualification existing under the present law of a physician occupying the position of President of the Board of Health in New York City. It was laid over for action at the second meeting in May.

Further Improvements in Microscopical Technique.—Dr. Henry G. Piffard read the paper, which was illustrated by apparatus and lantern slides. (See p. 545.)

Dr. Piffard then threw numerous lantern views on the screen, partly in illustration of his paper.

Dr. Stern was called upon to open the discussion. He said he had used the new mounting medium, liquid-ambar, with such extraordinary results that he expected hereafter to employ it altogether. With it he had been able to detect clearly outlines of structure which under Canada balsam had been very faint. He asked Dr. Piffard why one could not get critical illumination with Abbe's condenser.

Dr. Piffard, in replying, said that one could not obtain critical illumination with a condenser which was not correct, and Abbe's was such.

Dr. Fordyce spoke next, and said he thought that all who worked with the microscope, and especially those who did critical work, were greatly indebted to Dr. Piffard for technique of illumination, mounting medium, etc. Formerly, when using lenses made by the Germans, he had been unable to obtain satisfactory microphotographs, but since using those made by Spencer, after the suggestion of Dr. Piffard, he had been able to obtain exceedingly satisfactory microphotographs.

Mr. C. F. Cox was called upon by the President as a gentleman who had had experience in microscopy. Mr. Cox said he had been much impressed with the quotation made by Dr. Piffard from Abbe, and which had been accepted as orthodox, to the effect that we could not see anything correctly through the microscope if its diameter was less than $\frac{1}{2500}$ of an inch. While Dr. Piffard had not said that he was or was not orthodox, Mr. Cox was free to state that personally he was not. He had come to trust the microscope further. If it was true, as Abbe claimed, that our lenses were unable to take up all the refractive rays which left the object, and if it was necessary that they should take up all the refractive rays in order that the image should be a true picture of the object, then, of course, we were working very much in the dark. The speaker, however, believed that we saw much more correctly than the authorities had given us credit for, and he agreed with Dr. Piffard in thinking that there was a great deal to be gained by learning to operate these very wide-angle objectives. It was those who were wedded to the old theory of penetration, of seeing things in

stereoscopic relief, who were still working with the old-fashioned narrow-angle objective. While they did good work, they nevertheless missed a great deal which those gained by widening the angle of the lens. He would call attention to one advantage of widening the angle which had not been mentioned by Dr. Piffard this evening, namely, that while one saw less and less in depth he was yet able to separate the object more distinctly into its layers, and thereby accomplish what otherwise would have to be done mechanically with the microtome. Mr. Cox said he was a little sceptical about the value of wide-angle condensers, but he was fully in accord with Dr. Piffard with regard to the value of wide-angle objectives.

Dr. F. D. Skeel testified to the improvements made in lenses in this country, and said that under new technique he was able to carry out his examinations of the tubercle bacillus with a quarter-inch lens, a statement which a few years ago would have been regarded as moonshine. He was inclined to agree with Mr. Cox in his heretical views.

Mr. Bennett, who had made a study of diatoms, etc., testified to the value of the new media.

Dr. Piffard, in some concluding remarks, said he had found it difficult to free himself of the notion that what was needed in our lenses was penetration, until in the frontispiece of Carpenter's work he had observed two photographs, one taken with a lens of low aperture, the other with a lens of high aperture, both with the same magnifying power. The superiority of the one taken with the lens of high aperture was most striking. The highest aperture practical in a given case should be used if we would differentiate structure.

Therapeutic Hints.

Incontinence depending on lack of control in vesical sphincter. Tincture of cantharides every eight hours, provided stomach, bladder, and kidneys are free from inflammation.—Hare.

Snake-bite.—One drop of the gall of a rattlesnake applied to the wound is said by the *Scientific American* to be a cure. The gall-bladder entire can be preserved in alcohol. It is not stated whether it must be the gall of the snake that bit you.

Aluminol is considered almost a specific in gonorrhœa used as an injection of from one to twenty per cent. It has also been used with benefit in parasitic skin diseases, as well as psoriasis, prurigo, eczema, and ulcerations.—Heinz.

Peppermint Oil in one per cent. strength, combined with creosote, glycerine, chloroform, and alcohol, is recommended for inhalation in phthisis.—Braddon.

Diabetics are poor subjects for anæsthesia. Coma is apt to follow.

Quinine Pills made with aromatic sulphuric acid can be broken up at time of using and readily given to children with a little brown sugar or chocolate.—Bond.

Kola Extract, fifteen grains, sirup of quince, two ounces, given in teaspoonful doses, for chronic diarrhœa of infants.—Combemale.

Idiopathic Enlargement of the Heart.—The Schott treatment, by baths and gymnastics, seems specially serviceable in this affection before compensation has become irretrievably lost.—Babcock.

Oil of Cinnamon, while not a germicide, is a good mucous-membrane antiseptic in 1 to 500 solution, especially in infective varieties of nasal, laryngeal, and aural affections.—Kyle.

Gonorrhœal Vaginitis.—

℞. Potass. permangan. ..... gm. x.
Aquæ dest. ..... gm. cc.
M. Sig.: A tablespoonful for two quarts of water.

This is the best remedy, but it soils linen. In rebellious cases, or when it is necessary to act rapidly, a speculum is introduced and the vagina is painted with a solution of silver nitrate (two grammes in thirty grammes of water). Before withdrawing the speculum, a large tampon saturated with the following is introduced:

℞. Acidi tannici ..... gm. ij.
Cocain. hydroch. ..... ctgm. x.
Glycerini. ..... gm. cxx.
M. This tampon should be left in position two days.

—Lutaud.

Glaucoma.—When inflammatory iridectomy is the only treatment to be considered, it should be done at the earliest possible moment. To relieve pain, dry heat or the brief application of cloths wrung out in very hot water will be found best, but operation alone will give complete rest.—Jackson.

Pterygium.—Eye wash of bichloride of mercury (1 to 4,000) combined with cocaine and morphine. Four cases cured.—Balis.

Nuclein gives prompt and decided results in malarial fever.—Wilson.

Chloralamid succeeds in arresting night-sweats in over half the cases. Thirty to thirty-five grains were given at bed-time. Agaricin gave still better results, controlling the sweating in three-fourths of the trials. One-twelfth grain in pill-form at bed-time.—Conkling.

Compound Rhubarb Powder and careful dieting three days before operation prevent chloroform nausea.—Stern.

Stridulous Laryngitis.—Sixty grains of potassium bromide daily to a child of four and a half years, continued in large doses for five to eight days.—Huchard.

Erythema of Persistent Nature.—Quinine, thirty grains daily, in five-grain doses.—Payne.

Acne.—Superfatted menthol-eucalyptol soap when skin is inflamed.—Mackenzie.

Jugulate Pneumonia by Large Doses of Digitalis.—Tablespoonful of infusion (made with one drachm of leaves in seven and a half ounces of water) every half hour. Mortality a little over two per cent. and cure in three days.—Petresco.

Digitalis and Heart Tonics are singularly inefficacious in irregularities of heart following influenza. Digitalis is not only useless but harmful.—Sansom.

Bronchitis.—

℞. Phenol salicylate. ..... 3 j.
Terpin hydrate ..... 3 j.
Codein sulphate. ..... gr. ij.
M. Make twenty capsules or pills.
Dose.—One every four hours.

—Solis-Cohen.

Peripheral Neuritis.—Strychnine, grain $\frac{1}{30}$ to $\frac{1}{20}$, three times daily.—Stodart Walker.

Delirium Tremens—Chloralose four to nine grains.—Haskovec.

Iodide of Potassium, when it causes coryza and depression, can be best given with nux vomica and citrate of iron and ammonia.—Hardaway.

Vomiting of Pregnancy.—Chloral per rectum.—Parvin.

Guaiacol locally in follicular tonsillitis, one or two applications and cure within forty-eight hours.—Raymond.

Cephalalgia.—Cannabis indica is useful in all forms, gr. $\frac{1}{12}$ to gr. $\frac{1}{4}$.—Mackenzie.

Gonococci are destroyed in two hours by a one per cent. solution of creosote in hamamelis with boric acid. —*Pacific Medical Journal.*

Neurasthenic Debility.

℞. Acid phosphate..... ʒ j.
Ext. cocæ liquid..... ʒ ss.
Ext. damian. liquid..... ʒ ss.
Tr. nucis vomic..... ♏ x.
Syrup. zingib..... ʒ j.
Aq.....ad ʒ ss.
Ft. dosis. S.: To be taken in water at 11 A.M. and 6 P.M.

—Sir Andrew Clark.

Dipsomania.—Strophanthus in seven-minim doses cuts short the attack, produces nausea without ability to vomit, sweating, and not only loss of desire for alcohol, but disgust for it.—Skworzow.

Heart Sedatives.—Nitroglycerine is a sedative and not a stimulant. Digitalis is much abused. In excessive hypertrophy of sedentary individuals after a life of active exercise aconite acts well. Next to aconite as a sedative come gelsemium and then veratrum viride. —Hare.

Sepsis patients bear chloroform badly. "Half narcosis" is advised for minor procedures.—Mikulicz.

Iodide of Potassium given alone or in tablet form is apt to irritate and to be very slow of absorption. The following potable form of administration is advised:

℞. Potassii iodid..... gr. v.
Spirit. ammon. aromat..... ♏ xv.
Tinct. gentian. comp.....ad ʒ j.
Ft. dosis. S.: To be taken in a wineglassful of water.

—The Practitioner.

Lupus with disseminated nodules is best treated by curettage with a small, fine instrument which will enucleate the nodules. Cautery with chloride of zinc applied by means of a brush made with cotton should complete the operation.—Dubreuilh.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MEETING OF ROYAL COLLEGE OF PHYSICIANS—THE PRESIDENTIAL ELECTION AND ADDRESS—MEDICAL SOCIETY—A NEW NOSE—MEDICO-CHIRURGICAL SOCIETY—PELVIC HYDATIDS—LEPROSY—PRIZES—HYDROPHOBIA.

London, April 13, 1895.

Our Easter holidays have begun. Many left town on Thursday, but the earlier part of the week was full enough. The College of Physicians, to which precedence is due on the principle of *seniores priores*, had an "extraordinary comitia" on Monday, when Sir R. Reynolds was re-elected to the presidency by a practically unanimous vote—76 to 4—and then delivered his annual address. Before this he proposed the resolution of sympathy with the sister college on account of the decease of their President, Mr. Hulke. In the address it is usual to allude to Fellows who have died during the year, and Sir R. Reynolds gracefully mentioned the merits of Drs. Brown-Séquard, W. J. Little, O. Sturges, Bissett Hawkins, and Hack Tuke. He then made a new departure by alluding to a deceased member, Dr. Greenhill, the great scholar, sanitarian, and physician, whose death at Hastings I have previously recorded, and who was once offered the Fellowship, but declined it. The President did well to allude to this eminent scholar, who would have conferred distinction on the college which would not increase his renown. Perhaps at an earlier period he might have accepted, but what could a delayed compliment have seemed to such a man? The decennial revision of the nomenclature of diseases was stated to be ready to issue in a few days. The college undertook to publish the "Life of Sir Henry Halford," which has been written by Dr. Munk. Sir Henry's presidency was the longest in the history of the college, extending over twenty-four years, and he was physician to four successive British sovereigns. His life, therefore, from the facile pen of Dr. Munk, is likely to be full of interest.

On Monday there was a goodly show of cases at the medical society. Among them—a rare triumph for Mr. Bloxham—a case in which he had transplanted a finger to make a new nose. An attempt had been made to repair the damage by a flap from the forehead. When he came under the care of Mr. Bloxham an endeavor was first made to utilize a newly amputated finger, but without success; whereupon the patient suggested trying a stiff finger of his own. This was carefully prepared and placed in position, and kept there until adhesion took place, after which it was amputated and trimmed. The result is satisfactory to both patient and surgeon.

On Tuesday, pelvic hydatids were discussed at the Medico-Chirurgical apropos of a case related by Mr. R. Harrison, who in October last made an incision through the perineum as if for a lateral lithotomy, but without opening the urethra. About half a gallon of fluid and cysts was evacuated, and then the cavity was washed out and drained. The cavity contracted and healed and the man is now well. Mr. Harrison thought this opening better than through the rectum or abdominal wall, and he was supported by Mr. Durham and Mr. Hutchinson, who also said that though living hydatid cysts might sometimes be cured by simple puncture, dead ones must be completely emptied. Mr. Haward agreed to the necessity for complete evacuation, and mentioned a case he had emptied through the abdominal wall, adding that if the hydatid projected into the abdomen, the prospect of this opening was good, and any abdominal cyst being present could be treated at the same time, while drainage was easily effected.

Dr. J. Harley had collected some two hundred cases of hydatid tumors, and said cure could only be effected by removal of the parent cyst.

The award of prizes by a committee appointed by the National Leprosy Fund is announced. Dr. Impey, of Robbin Island, takes the prize for the essay on "Leprosy in South Africa;" Dr. George Newman, on its extinction in the British Islands; Dr. Ehlers, on its prevalence in Iceland: Dr. Thompson, in Australia; and Dr. Cantlie, on the conditions in China, Batavia, etc. The prizes on some other subjects were not awarded.

The Radcliffe Travelling Fellowship at Oxford, a prize of great value, has been gained by A. C. Latham, of Balliol, who is a son of the late Downing Professor of Medicine at Cambridge.

The Jacksonian Prize of the College of Surgeons has been awarded to Mr. Waring, demonstrator at St. Bartholomew's Hospital.

The Albert Medal of the Society of Arts has been awarded to Sir Joseph Lister for his application of antiseptic methods to surgery, and the medal was presented by the Prince of Wales on Tuesday last.

Mr. Victor Horsley presided on Monday at a meeting of the Society for the Prevention of Hydrophobia and the Reform of the Dog Laws. The object of the Society is the total extinction of rabies and hydrophobia by a system of universal muzzling for not less than a year, and by a rigid permanent quarantine.

Mr. E. F. S. McKay, surgeon to an English warvessel on Lake Nyassa, was killed recently by a lion while out shooting.

OUR PARIS LETTER.

(From our Special Correspondent.)

NEW REMEDIES—BICYCLING AND THE ACADEMY OF MEDICINE—METRORRHAGIA AND RUPTURED HYMEN CAUSED BY BICYCLE—HORSE SAUSAGE AND THE COMMITTEE ON HYGIENE—HOW TO DETECT HORSE MEAT—NEW PROCEDURE FOR THE STERILIZATION OF MILK, ETC.

PARIS, April 20, 1895.

PROFESSIONAL Paris is just now inundated with new remedies — advertisements in medical journals, prospectuses, cards, and pamphlets arrive by post several times a day, generally accompanied by samples of the remedy, which usually is vaunted to be applicable to a great variety of diseases. The latest and most interesting of these are Kinkélibah, a remedy to be prescribed in hæmaturic bilious fever, and Maté wine, a muscular tonic. Dr. Heckel, who has had a large experience with the kinkélibah plant in Africa, near Dakar, and at the St. Louis Hospital in Senegal, advises its exhibition to Europeans either when hæmaturia complicates ordinary bilious fever, or when hæmaturic bilious fever is declared *ab initio*, or as a prophylactic in all bilious or malarial districts. The leaves, either dry or green, are used in decoction, and the ordinary dose as a prophylactic, is a *petit verre*, fasting, in the morning.

The other, the Maté de Douglas, is made from the leaves of the maté plant of Paraguay. The natives of South America make a liqueur by expressing the plant, and even chew the green leaves. The alkaloid matéine is the active principle, and those who use maté are able to undergo more fatigue and physical labor than otherwise. It is being largely experimented in Paris at the present moment, and is prescribed in all cases of muscular atony or weakness. It has the peculiarity of affecting almost exclusively the muscles, and imparting at the same time a general feeling of fitness and strength. The writer has used it with success in cases of cardiac weakness and relaxation of the laryngeal muscles, quite a common affection among tenors and sopranos, also in chronic constipation from want of tone in the muscular coat of the intestines. Both of these seem valuable remedies in the sea of worthless ones, and will doubtless find their way to America—in fact maté is already on its way there—and it will prove valuable in progressive muscular atrophy.

The bicycle craze is spreading, and several of our most eminent physicians may be seen almost any Sunday morning wheeling gracefully and quietly along the now shady avenues of the Bois de Boulogne.

No question has aroused more discussion and difference of opinion in the Academy of Medicine than that of bicycling—indeed it was discussed at several stated meetings, being warmly advocated by some, and as strongly condemned by others. The consensus of the Academy's opinion seems to be that moderate exercise on the bicycle is advisable in neurasthenia, anæmia, dyspepsia, gout, and obesity, in all cases of slowness of nutrition, and where moderate muscular movement is required. It is absolutely forbidden in phthisis, organic disease of the heart, and albuminuria. Married women and young girls are fast following the example set them by the men—the latter, especially. For them it is not only ill-suited but dangerous. The writer knows of two cases of metrorrhagia brought on by mild bicycling, and another of ruptured hymen from falling on the pummel. Some have immovable bicycles in their bedroom, the framework being screwed to the floor and the wheels moving just as on the road. The amount of injury done to the pelvic organs of young girls just reaching womanhood will not be long in making itself felt in the shape of uterine versions and flexions, or cellulitis, to say nothing of other such serious complications as those mentioned above. The Parisian gynecologists will undoubtedly soon have more than they can conveniently attend to if matters continue as they have begun.

The Council of Hygiene have solicited the Administration to impose upon makers of sausage-meat the obligation to declare the nature of the meat they put upon sale. It seems that there is a large industry of this kind in Paris, where twenty thousand horses a year are utilized in great part for the fabrication of sausages. This the Committee on Hygiene consider quite harmless; only the competition is so great that butchers sell pork sausage for horse sausage, which for some reasons is more desirable. A chemical procedure has, however, been discovered, and the fraud can easily be detected by means of iodine, which colors a reaction paper a red-brown, shading toward violet, when dipped in horse bouillon, and reacts differently upon the paper first imbibed with beef or mutton bouillon. At a recent dinner given by men engaged in this business, every dish, from the soup to the dessert, was made from some organ of the horse. The fact that the muscular tissue of the horse, some of his organs and his intestines often contain the eggs of different helminths, seems to be considered of no importance whatever by the Committee on Hygiene, or to have escaped their attention altogether.

The sterilization of milk is also attracting the attention of the profession and the public, especially as several of the great milk companies are furnishing adulterated milk. The ordinary process of sterilization is by heat, which should not exceed 100° C.; but a process far superior has been proposed by an engineer, M. Villon; it consists of treating the milk by oxygen under pressure, which causes no essential alteration whatever, an important point in the alimentation of sick people and new-born babes.

PERSONAL EXPERIENCES WITH A GLASS EYE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: It seems to me that a great deal of what we see in medical journals about how artificial eyes should be kept, is humbuggery. But then I am not a physician but only a wearer of a glass eye. Keep them in a weak solution of boric acid, at night, we read. I was told by the manufacturer to keep mine in water, and did, every night, for a number of years. During these years the statement that an eye lasts about six months was true in my case too. Now I don't keep them in water and they last four times as long as that. I state the facts; others may do the explaining.

My eye is laid on a piece of oil-cloth at night. When I remove it, it is washed in plain cold water. When I make my toilet in the morning the cavity is well washed with water to which perhaps a little soap has been added, and the eye also washed again and inserted in its place.

I have never used antiseptics and have never suffered from sepsis of the cavity. Neither do I wipe the eye with cotton. That may explain the necessity of my removing the eye in company as mentioned below.

My "relay" I keep wrapped in tissue (toilet) paper in a little box made for eyes and lined with cotton velvet. When I wish to use it, I wash it in water and slip it in.

A unique experience was mine when I kept my eye in a glass of water. I awoke one morning to find the water in the glass frozen solid. After some handling the glass became slightly warmed and the cake of ice slipped out into my hands. There I had a lump of ice with my eye in the middle of it, just as we see fish frozen in cakes of ice in restaurants. It was time for me to be at business and there was no fire in the room. I broke the ice from all around the eye and finally succeeded in working it out. This could not have happened anywhere except in the South, where the people

are so hospitable that the weather comes in and makes itself at home, frequently bringing its things and spending the night.

A great deal is said about the patient providing himself with a pin, a hook, or a derrick, or some other means of lifting the eye out of its socket. I can sit in a room full of people and with nothing in my hand but a silk handkerchief, take out my eye, remove any mucous discharge which may have accumulated on it, swab out the cavity and replace the eye, and the company will hardly notice that I have done more than brushed away a passing tear. In doing this only one hand is used.

In handling my eye with my left hand one day it fell. I made a grab at it with my right, but instead of catching it on the fly I struck it a blow which sent it whizzing across the room until it was stopped by the wall. With a clear ringing sound it fell to the floor, perhaps twelve or fifteen feet from where I was standing—intact.

An intimate friend of mine sat near me one day and after looking me intently in the face said: "I heard that you wore a glass eye, but I see that it is not so." "You were correctly informed," I replied. "Which one is it?" he asked. With a pencil which I had in my hand I tapped the vitreous optic audibly. He was assured, but said he didn't see how a glass eye could have veins in it.

Having but one eye is a great hardship and a glass eye causes much embarrassment at times, but when a cinder gets into it how easy and painless it is to slip the eye out, brush the cinder off, and replace it. When a cinder gets into the other eye and causes so much pain, one almost wishes for the time being that too were a glass eye so that he might rid himself of his agony. But he doesn't think this too loud.

SILICA.

NEW YORK, April 18, 1895.

ON THE ACTION OF PERIODIC INDUCED CURRENTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I would like to say, *apropos* of Dr. Goelet's paper "On the Action of Periodic Induced Currents," etc., that the "modern induction apparatus, so constructed as to give ten different currents from as many different lengths and three sizes of wire," is far from being a modern suggestion in the ordinary acceptation of the term as applied to apparatus for medical purposes. For at least twenty years this form of coil has been widely used, and in the MEDICAL RECORD of November 8, 1884, will be found the first detailed description of its construction and some therapeutical considerations that I gave in regard to the differential indications for the use of the currents from the different combinations. In the light of our present knowledge some of these considerations seem very crude, but they are, in the main, as correct now as they seemed to be then.

The only improvements that have been made in the construction of these admirable coils is the greatly increased length of the terminal or finest coil of wire, and its better adaptation for gynecological work. These improvements I fully described in the *New York Medical Journal* of May 13, 1893, and August 18, 1894.

A. D. ROCKWELL, M.D.

April 22, 1895.

GAS ASPHYXIATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: By an account I have just read of two Italians suffocated by gas in a down-town lodging-house, I am reminded of a case of gas-poisoning I was called to last summer. After the patient had been restored to consciousness and had disavowed all intent at self-destruction, I investigated the chandelier of the sleeping-room and found that two of the keys were so deficient in action that when turned until brought to a full stop the outlet through the burner was left wide open for the gas to escape. The person occupying the room for the first time, and not knowing this unusual state of things, turns out his light, keeps on turning and goes to bed—perhaps never to get up again alive. In the case I refer to, the hotel people seemed to take little interest in the matter, though promising to have the defect remedied. I have since found several like instances, and have no doubt the city is full of burners equally calculated to deceive.

Would it not be a good plan for the MEDICAL RECORD to inaugurate an Anti-asphyxiation Association to urge proper inspection of gas-burners for the protection of the unwary?

C. W. A.

April 15, 1895.

THE URIC-ACID DIATHESIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: To your article on "The Uric-Acid Diathesis," in your issue of April 6th, I should like to add a suggestion as to treatment. It has been my experience that the application of a solution of ol. sinapis ess., ʒ j., spts. rect., ʒ xiv., gives the patient a quick relief which is very gratifying to both himself and his physician. Saturate a gauze compress of about three layers and envelop the joint, and after an application of five to ten minutes remove and apply absorbent cotton. Those who will try it will find it the most pleasant way of applying warmth, and as there is no manipulation of the joint nor fear of blistering if only the gauze be used, the patient will be appreciative. My theory of its action is that by its stimulation of the cutaneous circulation the lymph circulation is secondarily stimulated, thereby causing the biurate crystals to be taken up from the synovial sac and dissolved.

JAY O. NELSON, M.D.

April 19, 1895.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending April 27, 1895.

	Cases.	Deaths.
Tuberculosis	109	105
Typhoid fever	7	3
Scarlet fever	101	12
Cerebro-spinal meningitis	2	4
Measles	231	19
Diphtheria	214	28

Bright's Disease a Blood Disease.—Professor Semmola asserts that the fundamental pathological condition necessary for the passage of albumin through the kidneys—and hence for the production of Bright's albuminuria—is the morbid diffusibility of the sero-albumin which is a true dyscrasia in Bright's disease and a primary etiological condition. This view is for the most part confirmed by the latest investigations of Freund on the changes of the blood in Bright's disease. Semmola is convinced that in the majority of cases—acute infectious diseases, toxic, rheumatic, and gouty dyscrasias—the albuminuria always arises from modification in the diffusibility of sero-albumin, resulting from molecular alterations in the blood. When in these cases a nephritis exists, it is the result of the same diathetic condition, or due to the effect of the albuminuria on the kidneys. The egg albumin arising from nephritis, if no general dyscrasia is added to the arterio-sclerosis—arterial and gouty nephritis due to uric acid deposits—is very

small—0.30 to 0.50 per 1,000—while the amount of albumin secreted from a dyscrasial condition of the blood, when this is the primary effect of the disease, rises to two, to four, or even up to twenty grammes per litre, as is the case in Bright's disease. Continued subcutaneous injection of egg albumin causes albuminuric retinitis, and during life the animals experimented on show weakening of vision.

Russian Medical Journals.—The number of medical journals at present published in Russia is 38. Of these 20 are published in St. Petersburg, 5 at Moscow, 4 at Warsaw, 2 at Odessa, 2 at Charkoff, and 1 at Kasan, Kieff, Saratoff, Woronesz, and Pultawa, respectively. The oldest of them all is the *Medizinskoie Obozrenie*, which is twenty-one years old; next comes the *Russkaia Medizina*, which is in its nineteenth year, the *Vratch*, which is in its fifteenth, being third.

Blindness in France.—According to the *Progrès Médical*, the total number of blind persons in France is about forty thousand. Of these eighteen thousand are said to owe their affliction to the results of ophthalmia neonatorum.

The New Elements, Argon, Helium.—The earth spirit allows us to see more and more of the fabric that falls from his whirring loom, and we may, perhaps, soon be able to gather the scattered threads together and behold the full beauty of the great design. After the Faraday Medal had been presented to Lord Rayleigh at the annual meeting of the Chemical Society on March 27th, his co-worker in the discovery of argon, Professor Ramsay, was called upon to speak. (*Lancet.*) He announced that in his endeavors to discover a compound of argon he had experimented with a rare earth—clevite, we believe—which was said to yield nitrogen when acted upon by sulphuric acid. Instead of nitrogen, argon was evolved, but associated with it was some strange gas. On examination this turns out to be helium, the lightest of all the possible elements, whose existence, apart from the demands of chemical theory, had only been inferred from the line D_3 in the solar spectrum. It is the first of all the elements, for below this comes the hypothetical "protyle"—that pre-elementary cosmic stuff from which all the elements are supposed to have condensed. Although this small quantity of helium was only found a few days ago its existence has been confirmed by Professor Crookes, who has identified its spectrum, of which the most powerful line is that at a wave-length of 587.47 micro-millimetres. This line is almost identical with the well-known yellow sodium lines, and at first Professor Crookes thought that he had to deal with these, but all the magnifying power at his disposal was incapable of separating the lines into two, and careful measurement confirmed the suggestion that the line was no other than the D_3 line in the solar spectrum, attributed to an unknown element, provisionally termed helium.

Grave Robbery by Students.—Five students of the University Medical College of Kansas City were arrested, on November 23d, 1894, in Oak Grove Cemetery, in the act of robbing graves. The students were lodged in jail, but subsequently released on bail.

Intestinal Obstruction in Children.—Dr. Monti, after discussing the causes and general symptoms of intestinal obstruction in children, and accepting in the main the views of Leichtenstern, gives the following points as those which are of value in forming an opinion as to the site of the obstruction (*The British Medical Journal*): 1. In the lower part of the colon the first symptom of acute obstruction is painful colic, and the region of the abdomen in which the colic is first felt may afford some indication of the part of the colon obstructed. Vomiting does not occur until the colic has lasted for some hours or days; it is at first bile-stained then becomes foul, and finally feculent. Collapse sets in late; gaseous distention of the intestine begins in the colon, and at first it may be possible to make out that it is limited to the region occupied by the colon (flanks and epigastrium), but later the ileum also becomes distended, and the tympanites may reach a very high degree. In incomplete obstruction the symptoms are the same, but develop more slowly. Action of the bowels may occur, and be attended by temporary relief, especially of the tympanites. If the rectum be incompletely obstructed, constipation alternates with attacks of painful tenesmus, followed by the passage of small scybala. Circular constriction of the rectum causes the motions to be of small calibre. 2. Acute obstruction in the lower part of the ileum is attended with frequent attacks of painful colic, starting in the ileo-cæcal region. Each paroxysm of colic induces an attack of vomiting, the vomited matter being at first the contents of the stomach, but later fæcal. Collapse sets in early. The distention of the abdomen is most marked at first in the umbilical and hypogastric regions, but in time becomes general; it is not notably diminished by vomiting. At first several fæcal stools may be passed, but after a few days there is complete constipation. The quantity of urine is diminished after the first few hours or days, and there may eventually be suppression. When the obstruction is incomplete the colic may be as severe, and the movements of the coils of intestines perceptible. The degree of distention may vary greatly in a very short time, and this independently of the passage of a stool. The constipation, after lasting some days, may be succeeded by copious foul diarrhœa. 3. Acute obstruction in the duodenum or jejunum causes severe colicky pain, starting about the umbilicus and radiating toward the stomach. Vomiting comes on early, and is violent; the vomited matter is at first bile-stained, later it becomes foul smelling. Gaseous distention is slight, and is limited to the epigastrium. It may be very much diminished by vomiting, but collects again. The bowels may at first act spontaneously or after enema, but eventually there is complete constipation. Suppression of urine is established early. When the obstruction is not complete, the symptoms are similar but less severe. The colic is painful, and the vomiting, either in relation with the colic or independently, very frequent. The quantity of urine is diminished. There is no distention of the abdomen, and diarrhœa alternates with constipation. Monti considers that if a case is seen early much may be learned as to the probable seat of the obstruction by observing the way in which the tympanites develops.

Doctors' Unpaid Bills.—There is a law firm in the city whose business consists entirely of the collection of doctors' bills. One of the firm, curiously enough, is a constable.

"Does your business show that a majority of patients pay their accounts?" was asked of one of the firm.

"No. People have an idea that doctors get rich. If they do it is not from their fees. We have accounts from one doctor aggregating $43,800."—*Chicago Tribune.*

The Antiseptic Duel.—A curious account of the latest application of antiseptic surgery in duelling occurs in a recent number of the *Revue de Paris* in the novel entitled "L'Enfant de Volupté." The combatants enter a room in a house situated in the suburbs of Rome, and there find two surgeons busied in disinfecting the blades of the swords with a solution of carbolic acid in water, the odor filling the room. There is a table covered with bandages, dressings, vessels of carbolized water, and cases full of little glittering instruments of steel. The rivals strip to the waist, and the fight begins outside. One of them is wounded in the forearm, but so slightly that no dressing is required,

and the duel is about to be continued when the unwounded man inadvertently touches the ground with the point of his weapon. A surgeon instantly rushes forward with a sponge saturated with carbolic water and disinfects the blade afresh. In the next bout the same man is struck under the right nipple, but the point has touched a rib, which prevents it from penetrating. The surgeons then make pressure on the little wound, wash it with an antiseptic, put on a bit of pure strapping, and allow him to go on. In the last round the wounded man strikes his adversary full in the chest, and he falls back into the arms of his second. Presently the senior surgeon announces "penetrating wound of the chest at the level of the fourth left intercostal space, involving the surface of the lung." Perhaps in another encounter the novelist may advance a step further, have the candidates thoroughly scrubbed and disinfected overnight, and then despatched to their place of meeting in sterilized shirts.

The Oldest Man in the World.—A Frenchman now living in Russia is said to have attained the immense age of one hundred and twenty-six years. From a very interesting account of his life, just published in a Russian journal, it appears that he was born in Paris, on April 17, 1768. He has a vivid recollection of the "Terror." He joined Napoleon's army in 1798. He fought in the battles of Austerlitz and Jena, shared in the campaigns of Egypt and Spain, and finally was one of the four hundred thousand men who followed Napoleon to Moscow.

Are We Degenerating?— More than one recent writer is endeavoring to prove that the people of Europe are degenerating mentally, morally, and physically (*British Medical Journal*). Such views have been maintained by some of each generation of our forefathers since the time of Homer. Whether we are losing the delicacy of our literary and artistic tastes is too uncertain an inquiry, and if Europeans are diminishing in mental power they are certainly not diminishing in mental activity. The patience with which our studious youth submits to the often unreasonable exactions of examiners is a proof that at least they are willing and sometimes eager to labor under very heavy loads. But, leaving such difficult inquiries, let us rather take the data which the more exact observations of biological science have given us. Though the evidence is no doubt conflicting, the presumption that we are, on the whole, not degenerating seems to be strong. The working classes receive in the amount and purchasing power of their wages twice as much as they did fifty years ago; their food is better, and their houses healthier. In points of food, sanitation, and means of changing air and scene it may be safely said that every class now lives under better sanitary conditions than it did at the beginning of this century. Preventable diseases have much diminished; some, like scurvy and small-pox, have well-nigh disappeared; others, like syphilis, are milder in their attacks. The Registrar-General's reports also show a decrease in deaths from phthisis and scrofula. Studies in anthropology do not confirm the legend of giants in ancient times. It has been inferred from the size of old armor that the men of to-day are bigger than their ancestors. Broca maintained, from accurate observations, that the Parisians of the present time have larger skulls than those of the Middle Ages, but some of the skeletons of primeval man, especially those found in the south of France, have large and well-formed crania. Dentists generally hold that the teeth are now more prone to decay than formerly; but this may be owing to some change in the nature of the food, not entailing degeneration in other respects. It is well known that the average duration of human life has much increased, but this may be owing to greater care, better hygiene, and increased skill in medicine, adding to the lives of the more weakly members without increasing the tale of years of the healthy ones. During the controversy actively carried on about fifty years ago, as to the efficacy of bleeding, by some eminent physicians in inflammatory diseases, it was asserted that the type of disease had changed. Men could no longer bear the loss of blood as they could in previous generations. It is, however, to be noted that this assertion was made only by the advocates of phlebotomy, and only after experiments had proved that blood-letting could be discontinued without any increase in the mortality or duration of inflammatory diseases.

A great surgeon, the late Professor Syme, used to say that he totally disbelieved in this change of type, because men could bear surgical operations as well as they did thirty years before. That this also holds good of the present day is not wholly due to the mere improvement. We may safely say that men can bear up under severe shocks and injuries quite as well as they did in the last century. Considering the strain that modern civilized life exerts upon the nervous system, it would not be surprising if nervous diseases had become more common, though it has been found difficult to prove this by statistics. It has often been asserted that insanity is commoner than it used to be, but the studies of Dr. Hack Tuke and Dr. Rayner, which were noticed in these pages some time ago, tend to show that the increase in the number of the insane is due to the accumulation of lunatics in asylums, where they live longer under care than they used to. It appears, however, that the average number of recoveries in asylums is less than it used to be — an unwelcome piece of statistics somewhat difficult to explain. On the other hand, there are dangers to the healthy growth of some classes in our population which would be foolish to leave out of sight. The diminution of the rural population and of employments which harden the muscles, and the prevalence of intemperance in food and drink threaten to lower the tone of public health. In the large manufacturing towns we already see the results in a stunted and anæmic population. These sources of degeneration must be combated by putting in operation healthy influences, and teaching the people to attend to the laws of hygiene. On the whole, however, the healthy influences at work appear to be stronger than the morbific. So far from a general survey of society giving support to the belief that the rising generation are degenerating, the evidence appears to point to an opposite conclusion. The young people of our time are fonder of athletics than their parents were, and seem always to be creating more and more opportunities for out-door exercise. Such tastes are spreading from the upper and middle to the working classes, and the achievements recorded in the journals devoted to athletics and out-door sports show an actual increase in physical power. In running, jumping, skating, bicycling, swimming, and rowing there is no record which has not been beaten in the past ten years, as far as Europeans are concerned. In the beginning of this century people made much of Lord Byron swimming the Hellespont, but in our own day Captain Webb swam the Straits of Dover; and not long ago a member of our own profession, Dr. J. Daland, of Philadelphia, swam across the Straits of Messina. Girls in their teens now take much more healthy active exercise than their mothers or their grandmothers did, engaging in games or sports, such as lawn tennis, golf, rowing, and skating, which will have a good effect in the improvement of coming generations. The volunteer movement has had an invigorating effect upon our young men, and the prevalence of the military conscription upon the European Continent, though not without its evils, tends to cultivate physical strength, endurance, and manliness of character. Although causes are in operation which justly give rise to grave anxiety for the future there are as yet no serious proofs that the population of Europe is degenerating, and there are many gratifying signs of improvement.

MORNING DIARRHŒA.

By FRANCIS DELAFIELD, M.D.,

NEW YORK.

Definition.—I employ the term "Morning Diarrhœa," to designate a group of patients who, either continuously or at intervals, have, during the morning hours, one or more loose passages from the bowels composed of fecal matter and of fluid.

Lesions.—As the condition is not a fatal one we have to judge of the probable condition of the colon from the symptoms. The large quantity of fluid in the discharges indicates a considerable exudation of serum from the blood-vessels of the colon. The occasional presence of mucus denotes a morbid change in the functions of the mucus-producing glands. The complete change in the character of the movements, which in some patients occurs within twenty-four hours, would seem to show that there are no structural changes in the colon, while, on the other hand, the persistence of the diarrhœa in some cases points to the existence of a productive inflammation.

Etiology.—The disease is seen in New York in a large number of persons of all classes. I have not been able to determine any satisfactory reasons for its occurrence.

The Diarrhœa.—The discharges from the bowels are of large size, of brownish color, and composed of fluid mixed with fragments of fecal matter. Their odor is often offensive. The discharges come with a rush and are often accompanied by the escape of wind. In the more severe cases there is also from time to time a discharge of mucus. The passages are painless, or are preceded by colicky pains.

Varieties.—1. The simplest cases are those in which there is only one loose movement every morning after breakfast. This may go on continuously month after month, and year after year. Or there may be intervals of formed passages, or of constipation. There are no disturbances of the general health. Most of the patients do not seek for medical advice.

2. Much more uncomfortable is the condition of those patients who, instead of one loose movement after breakfast have several such movements. This condition also may continue for years, or may only occur from time to time. These patients are liable to a number of additional symptoms. In some of them there is a well-marked feeling of exhaustion after the passages. The exhaustion is so great that the patients are good for nothing all the morning, and it is not until the afternoon that they are able to attend to work or business. In others the colicky pains before the passages are very troublesome. The patients get up every morning with the knowledge that after breakfast they will have to go to the water-closet a number of times and in addition will have to suffer more or less pain. Instead of the colicky pains there may be a fixed pain referred almost constantly to some one part of the colon. This pain is so severe and so constant that it may lead to the suspicion of cancer, or of appendicitis.

Mental and nervous disturbances are associated with morning diarrhœa in two entirely different ways. First, There is a nervous condition caused by the diarrhœa, and which disappears when the diarrhœa is cured. The condition is that of apprehension, of fear. The fear may be of cancer, of peritonitis, of appendicitis, or of some other definite danger, or it may only be the feeling of fear without any special object. Second, There is a nervous condition which is not caused by the diarrhœa, but which makes the diarrhœa much worse. It is an irritability belonging to the individual, of such a character that any anxiety, or trouble, or fatigue will bring on the diarrhœa. In some patients the treatment of the diarrhœa is rendered hopeless by the frequent relapses due entirely to such a nervous condition.

3. As the disease becomes more marked the loose passages occur earlier in the morning. The patients wake up at four, five, or six o'clock in the morning with the feeling of an impending movement of the bowels. Then they go on to have several loose movements both before breakfast and after. The exhaustion and discomfort of the patients are very much increased by this early occurrence of the diarrhœa.

4. In some patients there is added after a time a sort of relation between the stomach and colon of such a character that whenever food is taken into the stomach there is a movement from the bowels. This is very annoying, for the patients are obliged suddenly to leave the table during the course of every meal.

5. The occasional presence of considerable mucus in the discharges belongs to the cases which last the longest and are the hardest to cure.

Treatment.—If the disease occurs in women, before beginning any medical treatment it is important to have cured any lacerations of the perineum or the cervix, displacements of the uterus, or disease of the Fallopian tubes which may exist. The methods of treatment which are ordinarily employed are :

1. *Change of Climate.*—The effects of this are often very satisfactory and in the milder cases very prompt. A person who has a morning diarrhœa for months may leave New York in the afternoon and the next morning begin to have formed passages. Unfortunately a return to the city may be followed by a return of the diarrhœa. In the more severe cases a prolonged residence in a dry inland climate may effect a cure.

2. *Diet.*—The plans of diet usually followed are : *a*, An exclusive diet of milk ; *b*, An exclusive diet of beef and hot water ; *c*, A diet composed of milk and meat alone ; *d*, A diet from which only the sugars and starches are excluded.

As regards the effects of treatment by diet we find : that some patients are cured, some are benefited for a time, in some there is no effect at all, some get worse.

3. In a small number of cases the diarrhœa can be cured by daily lavage of the stomach.

4. *Drugs.*—As a rule, the number of the passages can be checked for a moderate length of time by the preparations of opium. The improvement only lasts while the opium is taken, and it is evident that the use of this drug ought not to be continued for any length of time. The subnitrate of bismuth, the subgallate of bismuth and beta naphthol bismuth are said to give good results. I have not been very fortunate with them. Salol and naphthalin answer well in some cases, but have absolutely no effect in others. Arsenic, quinine, ipecac, belladonna, and cannabis are all very useful drugs. The drug which has given me the best results is castor-oil in doses of from five to ten drops.

PERNICIOUS DELAY IN SURGICAL CASES.

Presidential Address to the Medical and Chirurgical Faculty of Maryland.

By ROBERT W. JOHNSON, A.B., M.D.,

Professor of Principles and Practice of Surgery, Baltimore Medical College.

In casting about for a subject that would interest a body made up of medical and surgical components one naturally explores the border line where these two departments of our common science meet.

Appendicitis, so long found only in the medical side of our hospitals, is now peopling the surgical ward; while diphtheria is losing some of its surgical aspects in the advent of antitoxin, and it may not be Utopian to prophesy that the twentieth century will find an amalgamated physician and surgeon, whose hobby will be a Pravaz syringe, sired by instrument-case out of medicine-chest. The rendezvous of physician and surgeon is with local lesions rather than constitutional troubles, the vast majority of surgical troubles having their start in spots, and by the laws of their existence requiring time to spread from their point of origin to the system at large. Indeed, disease generally begins in one spot; the reason for our not appreciating this more thoroughly is that until we have evidences of constitutional infection, as in the eruption of exanthemata, our attention is not called to it; not until it has smuggled itself past the ports of entry are we able to lay hands on it and possibly arrest its progress. It is true the glandular system, in many instances, plays the part of quarantine, restraining, and perhaps building up barriers against infection, but with how much greater security could we act if we could pounce on the invader just as it reached our shores, before it set its poisonous foot upon the land, and fulfil the time-worn axiom, "Prevention is better than cure." We can scarcely hope that in our day and generation our power of diagnosis will be so accentuated that we can detect the very first lesions of cell life in time to eradicate the offender before it has involved its neighbor or its children's children in the subtle meshes of disease; we may still have to stand powerless before this Moloch we call prodromata until the score of pirates have grown to a great host, well on their way to the capital of the human republic; but with surgical diseases, accidents, and foreign growths their *début* is more marked and sooner realized; macroscopic rather than microscopic, tangible, capable of early eradication, and as serious in their demands as a foreign body in the larynx or the stoppage of hemorrhage.

As a border-land disease consider syphilis, with its local and constitutional phases. Take the so-called initial lesion of syphilis as an example. We know that chancre is not the true initial lesion, but the fruit of a lesion received some weeks before. We know that there is more or less constitutional infection already, but is it not good surgery to eradicate at the outset, or as near it as possible, at so slight a cost of tissue and risk, this plant whence further infection, like the proceeds of a baneful distillery, are distributed over the whole lymphatic system? We may not check it, but I fail to see any argument that prohibits us from stamping out the undeveloped possibilities of the sore. One is justified in waiting for developments for diagnosis, on the same principle as he might keep a dog-bite untouched in order to assure his patient that he had or had not hydrophobia. Such men as Jullien, Auspitz, Unna, Kölliker, Ehlers, and all, except Neumann, who took part in the discussion of Ehler's paper before the Tenth International Medical Congress in Berlin, 1890, believed in the theoretical possibility of either aborting syphilis, or rendering its course milder by excision of the chancre. Therefore, if authorities like Fournier believe that excision gives an average of one success in five, is it not pernicious delay to await developments and put diagnosis on a pedestal while the true end of our profession, treatment, goes begging?

Another local trouble that finds its often too tardy way, *via* the family physician, to the surgeon's hand is cancer. By the time the patient has hesitated to call her doctor's attention to her breast, plus the time the doctor has exhausted his internal and external applications, the lump has ceased to be a purely local trouble but is winding its devious and dismal path toward structures more essential to life than the breast-gland. Even here surgical science is not baffled. Halsted has lately shown the remarkable results in fifty cases of but six per cent. local recurrence, though the axillary gland had become more or less involved. He says:

"I sometimes ask physicians who regularly consult us why they never send us cancer of the breast. They reply, as a rule, that they see many such cases but supposed that they were incurable. We rarely meet a physician or surgeon who can testify to a single instance of positive cure of breast cancer. The conscientious physician could not under such circumstances advise his patient to be operated upon, and he was justified in treating her with salves and internal remedies. But now we can state positively that cancer of the breast is a curable disease, if operated upon properly and in time. I cannot emphasize too strongly the fact that internal metastasis occurs very early in cancer of the breast, and this is an additional reason for not losing a day in discussing the propriety of an operation.[1]"

That which is true of malignant disease of the breast is accentuated in like affection of more vital parts. "If any rule could be discovered for determining the approximate time when glandular infection is to be expected in malignant disease it would be of great service, but that period is so variable and the data so uncertain," says Curtis,[2] "that we can only predict it in the most general way." Yet physicians conspiring with patients let the cervix break down, the tongue ulcerate, or the testicle fungate before they are willing to seek surgical advice, and it is just such late operations that, failing in cure, cast opprobrium on our profession and make the laity less willing to undergo operation, quoting failures among their own family or acquaintance as justifying themselves. That the demurrage is due to selfishness I am unwilling to admit; that the physician desires to retain the case altogether in his own hands, and to receive thirty pieces of silver as a Judas, is beyond comprehension; but no matter whether the cause for delay be selfish or magnanimous, it is pernicious all the same because in the interim local lesions become constitutional and beyond the pale of operation.

Don't for a moment mistake the perhaps necessary delay, in getting your patient in the best possible condition for operation, for pernicious delay. A surgeon who wishes to take a pound or more of flesh from next the patient's heart on introduction might well be arrested for carrying concealed weapons. I plead not against conservatism but against procrastination, against the expectant treatment gone to seed, against fallacious excuses, as doubt as to diagnosis, etc. Gentlemen, the knife in these aseptic days is to the clean surgeon often what the stethoscope is to the physician; properly conducted incisions mean a definite and innocuous certainty instead of hap-hazard, *a priori*, surmises, and has the advantage of the instrument of Laënnec in that the scalpel is not only for diagnosis but is synchronously a cure.

Why, then, should we seek to illuminate the tissues with the brilliancy of our guesses, run the whole gamut of perhapses, that may have been justifiable in pre-aseptic days, when we have in our hands the means of rendering surety doubly sure, and, like Moses's rod, transform the flint into lucid streams by the mere stroke of a deft right hand?

[1] Annals of Surgery, November, 1894, p. 513.
[2] Medical Record, February 16, 1895.

Has aseptic surgery brought with it any temptation to pernicious delay in the treatment of wounds? It has—one I feel myself sometimes. All of you, who do any surgical work, whether as a specialty or in general practice, know what care and preparation must be taken to insure the desired results in your ideal wounds—even more in your suspected wounds—and with what mental satisfaction you see the finished product of your conscientious work (for you must have a surgical conscience to insure the letter and spirit of the law) in the limb, for instance, at rest with its proper strata of dressing. Then your thermometer becomes your guide, philosopher, and friend, a surgical compass; and you watch the possible variations due to fibrin-ferment fever with complacency until it is time for that to cease. Now comes the temptation to pernicious delay. When the temperature rise ceases to be explained in truth by that subtle metamorphosis of wounded tissue at the point of injury or operation, do you not sometimes strain your fibrin-ferment's reputation a little and try to excuse that variation on grounds which you endeavor to convince yourself are only transitory? Instead of recognizing at once that through some fault, perhaps in your technique, or some factor in your wound, you are dealing with pus infection, and what you should do is to remove that dressing now, drain, and if you cannot prevent suppuration, prepare at once for its treatment on old if not as self-commendatory lines. Delay in recognizing your mistake or your misfortune is pernicious, and it is better to blush at pus exposed than to endeavor to hide your error beneath a mass of dressing that does not pale the blush of inflammation nor stifle the tell-tale temperature chart. I believe if we are sensitive on this point, willing to accept the verdict of the thermometer, we can often close our suspected wounds and have them heal by blood-clot or per primam, when pernicious delay at the outset would allow them to suppurate, or delay in recognizing first evidences of suppuration a little later endangers the patient's life.

See how the front is changed in treating gangrene. "The line of demarcation, the line of demarcation," was the shibboleth in every case. Men hesitated to amputate, and some went so far as to let Nature do the whole operation. Senile gangrene was allowed to carry off patient after patient, while the surgeon stood helplessly by, or busied himself in relieving pain or mitigating odors as this black death wound its putrid coils around the foot and limb and beckoned the clear-minded but rotting sufferer to a grave that presented all the horrors of anticipation. Now the dictum is, amputate high up outside the zone of infection, and beyond the vitiated arteries, if the general condition admit. So in spreading traumatic gangrene, "there is perhaps no affection in the whole domain of surgery which demands such prompt interference in order to avert impending death."[1]

There is a delay that is pernicious in the treatment of fractures. Men are indisposed to put them up in fixed dressings on account of the liability to swelling and possible gangrene, but I think I can state a general principle that will cover these cases. A fixed dressing may be applied to any fracture at the outset that admits of a fixed dressing at any time during its treatment, provided sufficient cotton wadding or padding be used at its first application to prevent pressure on prominent parts, and provided said dressing be split down the front immediately after its application. By this means ample room is made for any swelling which is not desirable in itself and the limb is allowed to expand in the expansive case. To put on a splint and keep removing it is the worst possible surgery; a fixed plaster, starch, or other hard encasement is the secret of success in treating fractures, with fenestra if infected, reducing the circumference if the limb shrink.

To surgeons of the early part of this century the cavities of the body were cabinets of mystery containing organs of which they knew a little, and surrounded by that uncanny vail of serous membrane that seemed to be tinder in the presence of inflammation. It was no wonder, then, they hesitated to convert a simple depressed fracture of the skull into a compound one to make sure there was a fragment pressing on the brain. They feared suppuration, rightly perhaps, more than they did doubt; they use the expression, give the patient the benefit of the doubt—a doubtful benefit, then, a positive injustice now. What more pernicious than delay in head injuries, of the vault for instance, than to await the appearance of late symptoms to decide between concussion and compression, or more pernicious than to allow a depressed bone to remain depressed until epilepsy or cerebral abscess point out our mistake? Can anything be simpler than to enlarge your scalp wound, if compound, or make one if in doubt, and see the surface of the skull, and then decide as to whether trephining shall or shall not be done? If your technique is perfect—and with the simple means of disinfection, anyone can acquire asepticism who religiously cultivates it—you have done your case no harm should you find nothing. You have saved a life perhaps if you have not merely trusted to luck and have treated the condition you have found presenting at the bottom of your wound.

The cavity of the thorax, thanks to the mechanical action of heart and lungs, together with the illuminating genius of Laënnac, was opened to the medical fraternity at an earlier date than the cranial or abdominal cavity; but paradoxical as it may seem, the very conditions that make diagnosis surer render treatment, at least surgical treatment, less efficient. The heart is much more a stranger to the scalpel than the brain, and operations on the lungs do not compare in frequency with the thousands of laparotomies done monthly. In spite of this statement the abdominal cavity is the great guess centre for the general practitioner, and is the object of more pernicious delay than all the other parts of the body put together. From the fact that it is lined by the awe-inspiring peritoneum, with its rapid absorptive power, containing a battery of flexible tubes as essential to life as are the convolutions of a boiler to the steam-engine, that it is menaced by fears within and foes without in the form of microscopic amœba coli and bacillus commune to the tangible appendix and the hernial rings, that its action for evil in intestinal lesions is even more rapid than its continuous action for good in health—all these factors, I say, render it, *par excellence*, the most dangerous field for delay, a very prairie where a spark may kindle a conflagration in a moment. Let me here protest against closing the vistas of diagnosis by the indiscriminate use of opium. As if the abdomen were not sphinx-like enough in its symptoms, we mask our eyes and muffle our ears by checking pain, one of the most important means for differential diagnosis, and bask in the mist of a fool's paradise, fancying that because we have quieted our sentinel we have overcome the enemy. Whenever it is possible, then, unless shock is so severe that you cannot, avoid opium until you make your diagnosis at least, and then it becomes a boon. There is no drug in the whole list of medicines that is so great a blessing, rightly used, and none so contributing to pernicious delay than the poppy and its derivatives if misapplied.

There is only one way to be certain of what is going on in the abdomen, and that is by exploratory incision in grave cases, and in this class laparotomy presents less dangers under modern technique than uncertainty, and I mean by that an operation done in time, not a sort of ante-mortem examination after shock and sepsis have wrought their deadly work on one who has called on you for help. What can you do by guesswork, or by delay, or by manipulation, or by opium, or even by the legitimate mechanical means of injection, or massage, in volvulus, or intussusception, or constricting bands, or strangulated hernia, or malignant growths, or gall-stones, or penetrating gun-shot wounds by large missiles,

[1] American Text-Book of Surgery, p. 55.

especially if standing two feet from the body you profoundly guess at the contents and action of a cabinet full of secret springs and wheels within wheels? You must overcome your prejudices against the scalpel just as your fathers did theirs against the microscope, and your grandfathers against the stethoscope; but together with your prejudices you must lay aside your old notions of "laudable" pus and embrace the idea of damnable pus. The latter half of the nineteenth century has done nothing for you in surgery if you retain the methods of the earlier half. Lister has lived in vain for you, Pasteur has labored in vain for you and your *clientèle*, Koch has astounded you in vain, unless you, as an individual operator, carry out the results of their laboratory and clinical work. Far better *is* guesswork, far better trusting to Providence, or opium, than to attempt modern operations with old methods, when the hand of the surgeon was more baneful than the serpent's tooth because of its intelligence devoid of knowledge which has since made it beneficent. You may say, Gentlemen of the Faculty, "that this is a twice-told tale. We all know this." Gentlemen, I reply, you do not act on it. There is no surgeon in this room, I venture to say, that has not had experience in operating for strangulated hernia, through a medical man who has dillydallied and procrastinated and perniciously delayed the operation until the patient was past praying for, and been greeted on opening the sac with a gush of feculent contents, the stinking fruit of unpardonable delay. This very physician is possibly versed in the learning of the Egyptians, *au fait* with aphorisms of the school of Salernum, conversant with the life and times of John Hunter, more or less a user of the various ols and ines that flood the present drug-room, and yet so repugnant has the term operation, or so confiding has he been, even in mechanical cases, in the formula of the Pharmacopœia that he has stultified himself by attempting to substitute the day of salvation for the morrow of disaster.

Some months ago, in discussing laparotomy in perforating abdominal wounds, I was unwilling to subscribe to the dictum that *all* penetrating wounds of the abdominal cavity require laparotomy, not that I have any objection to the operation *per se*, if we content ourselves with simply opening the abdominal cavity and viewing its contents. It is rather because I feel that in small penetrating wounds, as after small shot, or a minute stab, we are in imminent danger of causing fecal extravasation from moving the bowel around in our search for minute openings, which, if left severely alone would close themselves either by extravasation of lymph between adjoining coils or by inversion of the intestinal coats before such untoward result took place. Of course this obtains only in lesions so small that the danger of extravasation is minimized if left alone. In by far the vast majority of cases of intestinal wounds, operation is called for at once, not waiting for sepsis to nullify our work.

If delay in beginning such an operation is pernicious what can be said of delay in finishing it? The more rapid our work is done in conjunction with thoroughness the better: hence we should not hesitate to accept any mechanical means, as Murphy's button or Senn's plate, instead of the longer shock-producing sutures so difficult to apply. We must not allow the bugbear of records to stand in our way even in desperate cases.

The proper treatment of appendicitis is a touchstone of a man's capacity, and I know of no law that covers each case, as each one presents problems to be grappled with individually; but, in a general way, appendicitis may be divided into the fulminating, the acute, the subacute, and chronic or recurrent varieties. There are two periods in appendicitis that may be called times of election: The first is before pus is formed and is at the outset of the disease, no matter what variety it may assume: the other is after the lymph-walls have enclosed the pus that has accumulated. Between these two conditions there is a time of excessive danger to the operator, *i.e.*, when pus is forming, and yet the barriers are not sufficiently strong to admit of any disturbance without risking the infection of the whole abdominal cavity. This is the time when most surgeons are called in, after the diagnosis is made by the physician, who has perhaps not had sufficient data to be certain before or has masked the danger signals by opium.

Fowler, in his excellent paper based on one hundred and sixty-nine cases, personally observed, divides acute appendicitis into four stages, according as the tunics of the appendix and its neighboring tissue become involved—endo-appendicitis, parietal appendicitis, peri-appendicitis, para-appendicitis. He goes on to say: "In addition to the fact that the disease may run through all four stages within three days, and the first three stages in forty-eight hours, there are especially dangerous conditions that may supervene or accidents which may occur even when the inflammation seems to be limited to the mucosa or submucosa."[1]

In regard to treatment, he says: "While the physician is generally first summoned to a patient suffering from appendicitis the responsibility of the treatment should be shared both by the physician and surgeon. The majority of cases should be treated surgically. Beyond the careful use of salines in the very commencement of the disease, and this only if the symptoms denote a mild type of the affection, the less medical treatment which cases of appendicitis receive the better. Above all things, the use of opium must be avoided as much as possible. Its use masks the progressive character of some of the important symptoms; with free use of the drug the patient's condition seemingly improves, but a sudden increase of pain followed by distention of the abdomen, accompanied by or followed by a rapid pulse and some rise of temperature, announce the occurrence of septic peritonitis."

It should not be forgotten that an exceptionally virulent infection may produce septic peritonitis with neither primary perforation of the appendix into the peritoneal cavity nor rupture of an abscess cavity. Delay in operative interference in such cases will certainly result in disaster, and interference may fail to save the patient.

The indications for operative interference during an attack of appendicitis may be summed up in a few words. As soon as the diagnosis of progressive appendicitis is assured the abdominal cavity should be opened and the appendix removed. If opium has been injudiciously administered and the progressive character of the case in hand is doubtful, it is better to err upon the side of safety and remove the appendix at once. The conditions present are usually beyond the power of nature to remedy, while in the hands of a surgeon who pays strict attention to aseptic detail of the operation the latter entails less risk to life than that which is involved in even a mild attack of appendicitis, which remains stationary at the end of twenty-four hours, with all its possibilities of lymphangitis, infection of the peritoneal cavity, retained muco-pus within the tube, and rupture of the latter into an unprotected peritoneal cavity, or ulceration and perforation, either from the presence of so-called coproliths or inspissated fecal matter imprisoned by constriction within the cavity of the appendix, or from gangrenous conditions alone.

In formulating a definite rule for action in the operative treatment of appendicitis many difficulties are met with. To operate too early may be to operate unnecessarily; but this is always preferable to operating too late, and hence unsuccessfully. The fact that operative procedures are quite safely performed when a distinctly outlined and encapsulated abscess cavity is present, provided the surgeon does not disturb its wall, has led Riches and Schmit, of Versailles, to adopt this pe-

[1] Annals of Surgery, vol. xix., No. 1, p. 8 et seq.

riod as the stage of election. These surgeons content themselves with simply emptying the pus cavity. On the other hand, many surgeons advocate operation as soon as the diagnosis of appendicitis is made, whatever its grade of severity.

A case demanding operation inside of twenty-four hours from the commencement of the attack is exceptional; but a case which is not practically well at the end of that time should be made the subject of operative interference. The surgeon should by no means limit himself to that period. (McBurney reports 14 recoveries by operation in 24 cases of general peritonitis after appendicitis.) In cases in which unusually severe symptoms, such as high temperature and a succession of rigors are conjoined with exquisite tenderness in the right iliac fossa (fulminating), and an anxious facial expression, the surgeon should not hesitate to give the patient the benefit of an early and radical operation.

When the patient is not seen by the surgeon until the third, fourth, or fifth day of the attack, the question as to whether or not operative procedure may be contra-indicated by the impossibility of removing the appendix without breaking down the adhesive barrier which has been thrown out, is one which is frequently encountered by those engaged in this class of work.

As very tersely stated by Richardson, we may be confronted by cases which are in such a condition as to be too late for the early operation and too early for a safe late operation. In deciding the question much will depend upon the experience of the operator, and the facilities which he may possess in the shape of skilled assistance and other requisites to meet all emergencies as they arise.[1] J. B. Deaver[2] says: "The first and most important of all is the necessity of early operation for those cases of acute appendicitis, whether in the initial attack or in an acute attack supervening upon a chronic appendicitis not immediately yielding to judicious purgation. The ravages of this affection are so rapid and so fatal that I can hardly express myself too strong upon this point."

The general trend of surgical opinion may be summed up in the opinion that in the fulminating form of appendicitis an early operation is demanded; that in the acute variety, that does not show marked improvement early, an operation is indicated. In the stage of abscess formation prior to the building of secure lymph partition, opinion is divided, with a leaning toward operative procedures by men sure of their technique and masters of the surroundings; that in the condition where we have abscess formed, well hemmed in by walls, the evacuation of the abscess, with or without the enucleation of the appendix, is the proper procedures. With chronic or relapsing appendicitis we have nothing to do in this paper, except the general principle to operate at the earliest indications. In all our dogmata we must bear in mind the two variables, the judgment and skill of the operator and the personal equation of the patient.

Time prevents the consideration of dangerous delay in other systems, as the genito-urinary or the portal, etc. For those who are beginning to detect evidences of pernicious delay, in ending this paper I must not bring it to a close before I remind them that there are certain tones that hold their tension all along the ages and echo through the corridors of time. Their key-note is either the despair of desertion or the ecstasy of deliverance. The individual, the me or mine, is perishing or saved. Can any wail be more human than that of Calvary? "Eloi, Eloi, lama sabachthani—My God, my God, why hast Thou forsaken me?" Can any ecstasy be more celestial than that trite shout of the Highland lassie before Lucknow, "Dinna ye hear the slogan?"

Night and day, my *confrères*, you are called on to save the individual. For God's sake let him not cry to you as a *Deus ex machina*, "Eloi, eloi, lama sabachthani," but bearing in your hands the fruit of ripened experience and faithful study, let your footfall, heralded by no pibroch, accompanied by no banners, saluted by no artillery, muffled, perhaps, by the snow-flake, be unto him as early, as opportune, as health-giving as was Havelock's relief to Lucknow.

THE SEXUAL CRIMINAL.

By JAMES WEIR, JR., M.D.,

OWENSBORO', KY.

Though a firm believer in polygenesis and the multiple inception of the human race, I, nevertheless, hold that pithecoid man, everywhere throughout the world, was, anatomically and structurally identical. All prehistoric skulls, whether unearthed in America or in the Old World, show that man was dolichocephalic or long-headed. They also show that primitive man was prognathous and that his orbital arches were greatly enlarged and developed. The structural characteristics enumerated above are also found in the primitive races yet inhabiting the earth, and most marked in those races that rank lowest in the scale of human intelligence and social economics. This latter fact is to be expected, for it is an acknowledged conclusion that the lower a race is in point of intellect, the nearer that race is to its primal ancestry. Again, the phenomenon of atavism or reversion teaches us—a mesocephalic race—that our savage ancestors were long-headed and prognathous; for, in the congenital criminal, emphatically an atavism, we plainly see an individual, anatomically and psychically, closely akin to the savage and barbarous peoples from whom we have been, unquestionably, evolved.

The white sexual criminal, and throughout this paper, I mean by sexual criminal, the individual who commits rape, shows, very plainly, to the eyes of those who are versed in such matters, the signs of physical and psychical degeneration. He may have been born degenerate with a bias toward criminality stamped indelibly on his psychic being, or, through excess, he may have engendered certain pathological conditions in his physical organism which make him tend toward anti-social acts. The white congenital sexual criminal commonly presents certain marked physical characteristics. I have personally examined two white men who had been guilty of rape and both of them were dolichocephalic and prognathous. Their orbital arches were greatly enlarged and their cheek-bones high and prominent. Their genetalia were abnormally developed, and the growth of hair on their bodies rank and thick. Both of them had fair hair and both had malformed ears; in one the lobes were long and pendulous, in the other there was complete absence of the antihelix. Both were below the average in point of intelligence. Says Ottolenghi of the sexual criminal: "On the whole anomalies of the genital organs have, in sexual offenders no small diagnostic importance, especially when united to other characteristics which distinguish them from the honest and criminals in general, as the greater frequency of fair hair, of malformed ears, of bichromatism of the iris, of blue eyes, of twisted noses, of facial asymmetry, of voluminous lower jaws, and of various neuroses, especially epilepsy." These men knew that they would probably suffer death in consequence of their crimes, yet, imprisoned and safe from mob violence, they became jovial and light-hearted, for all the world like children who had escaped, for the time being, well-merited punishment. The child-like nature of savages is well known, therefore I wish to emphasize this fact in these two criminals, for it tends to show the truth of that which I have declared before, *i.e.*, that the white sexual offender is, in the vast majority of cases, an example of psychic atavism.

Love is an unknown emotion both to the violator and to the savage; they are both instigated by lust.

In discussing the sensuality of criminals Havelock Ellis says: "Love, in its highest and strongest forms, seems to be extremely rare." When a man was asked if he really loved the woman for whose sake he had murdered her husband, he replied: "Oh, if you had seen her naked!" I asked one of the sexual criminals examined by me if he loved his victim. "No," he replied; "but her legs were very beautiful."

The criminal is perfectly well aware of the fact that rape is an anti-social act and that it will be severely punished, yet his savage lust, held in check by no moral restraint, will lead him to commit the act if opportunity offers, and he thinks that he can escape punishment. He will commit rape not only once, but many times if he can escape apprehension. I have in my possession a sketch of the skull of P. J——, a criminal, who, it is believed, raped no less than five different women. An engraving of this skull can be seen in my article on "Criminal Anthropology," in the MEDICAL RECORD, issue of January 13, 1894. This skull points, beyond a shadow of a doubt, to an atavism or reversion to an ancestral type. The Neanderthal skull and the skull of the Man of Spy, both prehistoric skulls, are startlingly like the skull of this modern violator.

False sentiment as well as the law declares that all men are brothers. Science declares that such a conclusion is absurd and fallacious. There is too marked a difference between the dolichocephalism and prognathism of the normal savage, the negro for instance, and the mesocephalism and orthognathism of the normal white man for fraternal relationship. I have pointed out the fact that the dolichocephalism, etc., of the white sexual criminal are abnormalities and the result of degeneration. The long head and the projecting jaws of the negro, however, are normal; they are anatomical characteristics peculiar to the negroid and other savage races. Again, the psychical abnormalities of the white sexual offender are occasioned by degeneration, while the mental habitudes of the negro violator are perfectly natural. It is time that mawkish sentiments were banished, and the negro placed in the category to which he belongs. The negro has had here in America some two hundreds of years in which to acquire civilization. What folly to place his psychical development on the same plane with that of the white man who has the advantage of him by several thousand years! Civilization, morals, are the result of evolution, of inherited experiences, therefore what arrant nonsense it is to suppose that the negro, who was a savage only yesterday, has become a moral and thoroughly civilized being to-day![1]

Native-born Americans, whose ancestors came from Great Britain and Europe, are remarkably free from the evil effects of degeneration, consequently the native-born white sexual criminal is of rare occurrence. The negro violator, on the other hand, is quite numerous, springing up everywhere in all of the Southern States, where his race is mostly domiciled. His criminality is not due to degeneration, but is the result of perfectly natural and, for him, normal mental habitudes. Let us study, for a moment, the psychology of this semi-civilized savage.

The childlike simplicity and happy-go-lucky carelessness of the negro, and I mean, throughout this paper, the true negro, not the half-breed, is notorious. The cares of to-day are sufficiently burdensome for him; he lets to-morrow take care of itself. Two hundred years of civilization have given him a thin, a very thin, veneer of superficial morality. In fact his moral nature about equals that of a white child five or six years old, who has no real knowledge of abstract ethics whatever. The negro cook who steals your flour, butter, sugar, and eggs does not consider her peculations to be thefts; she numbers such acts among her inalienable rights, though she is very careful to conceal as much as possible her petty rogueries. When she drops on her knees and asks God to pardon her, your butter, sugar, flour, and eggs do not form any portion of her burden of sin. The negro who robs your watermelon patch and your hen-roosts on Saturday night will be found Sunday morning in the deacons' corner of the sanctuary. His full, rich, sonorous voice will sound all the better in prayer and song, on account of the fat chicken and luscious watermelon that he has eaten before he donned his long-tailed coat and hied himself to church. His religion is pure and unadulterated superstition. God and the devil (Voodoo in some form or other), are equally objects of his superstitious regard.

The records of the police courts, wherever the laws against fornication are enforced, will show that the negro, both male and female, has little or no regard for virtue. Northern sentimentalists have declared that the slave-owning whites were to blame for this moral laxity. This is nonsense, for it is a well-known fact that three half-breeds are born to-day where there was one born during slave time, thus showing conclusively that the negro women voluntarily yield up their virtue. But why argue this question; the history of the world shows that the women of the lower races, wherever found, eagerly enter, as a general thing, into concubinage with men of the white race. The men of the lower races passionately desire the embraces of the women of the white race, and this accounts, in a measure, for the numerous rapes upon white women by negroes. The negro is rarely accused of committing rape on the females of his own race. The reason for this is found in the natural complaisance of the females of this race; the male being able to easily satisfy his desire without resorting to violence. For the same reason a white man is seldom guilty of raping a negro woman.

No amount of legislation will ever make people accept the negro as their social equal. Common-sense teaches them that he is their inferior, while science shows conclusively that he is of lower origin. Hence it happens that when a white girl is raped by a negro the disaster is simply appalling. She feels as though she had been dishonored and defiled by some monstrous beast; her moral courage is gone forever; her honor and her virtue can never be regained. These feelings are also entertained, to a certain extent, by her relatives, friends, and, in fact, by every white individual in the whole country.

Not long since, a young lady in a neighboring State was dragged from her horse, carried into the woods, choked into insensibility, and repeatedly ravished by a negro. She was found, half-dead, by a searching party late that night. Blood-hounds were put on the track of her assailant, he was caught, brought before her, identified by her, and at once hung. This young woman came near dying from her injuries, but finally recovered. She, however, never left her home again, but, soon after she was able to leave her bed, she went into an outhouse and hung herself. Her father came home, and on finding the dead body of his daughter seized his revolver and blew out his brains. The following night her brother drowned himself. Her relatives sold their real estate and personalty and left their native town forever.

The fear of the negro rape-fiend is general throughout the entire South. A remark of an aged negro shows me that this fear is by no means a baseless or groundless one. Said he to me, calling my attention to a young girl who was picking blackberries, "That girl is in danger. At this time of the year men's passions are hot. Some man might see her, seize her, and easily

[1] "One of the most generally applicable statements we can make with reference to the psychology of uncivilized man is that it shows, in a remarkable degree, what we may term a *vis inertiæ* as regards upward movement. Even so highly developed a type of mind as that of the Negro—submitted, too, as it has been in millions of individual cases to close contact with minds of the most progressive type, and enjoying as it has in many thousands of individual cases all the advantages of liberal education—has never, so far as I can ascertain, executed one single stroke of original work in any single department of intellectual activity."—Romanes: Mental Evolution in Man, p. 13.

drag her into that clump of bushes." This man, for the moment, forgot his superficial civilization and allowed me a glimpse of his real, savage nature. Had he been a younger man, and if this opportunity had offered, I have not the slightest doubt but that he would have seized the girl, dragged her into the clump of bushes which his lecherous old eyes had discovered, and ravished her.

I know a young woman who is compelled by force of circumstances to take long and solitary country rides. She never leaves home without placing a revolver on the buggy-seat by her side. In the South, women never go out after sundown without an escort. The violator and his savage lust is ever present to their minds. This is a fearful commentary on our boasted civilization, yet it is true in every particular. The sexual criminal, both black and white, is dangerous to society; so dangerous that the sooner he is destroyed the better it will be for society. The mad dog is not granted the formality of a legal trial before we blow out his brains. He is destroyed at once. The Malay who runs amuck is slain without mercy, society recognizing the fact that the end justifies the means.

It is by fear alone that the savage can be influenced. You cannot influence him by moral suasion, for he has no knowledge of morals; neither can you instil morality into him through the agency of punishments. The fear of death—sudden, violent, terrible—is about the only thing that will hold the sexual criminal in check and teach him that he must restrain his savage lust. The sexual criminal, both white and black, is a savage and should be treated as such. If the law is left to take its slow course, people become accustomed to the idea of that punishment which is eventually inflicted on the criminal and greet its consummation with indifference. But if the criminal is taken in the act of committing rape, or soon after, and is immediately punished for his crime, the lesson comes in the nature of a shock and is not soon forgotten. Punishment is meant, not only for the criminal, but for society also, and the more forcibly society is impressed by the punishment of crime, the more deterrent will the lesson become.

The question naturally arises: Does lynching act as a preventive and a protection against the crime of rape? My own personal observations, as well as those of many conservative men, both north and south, teach me that it does. For, if a violator is apprehended and lynched in a community, the crime of rape does not occur in that community for many years, or, if it does occur, the individual committing the outrage will be found to be either a stranger who has recently come into the community, or a young man who has reached maturity since the time of the last lynching. Statistics gathered from every section of the country show that a like result does not obtain when the sexual criminal is punished through due process of law. The lesson taught by lynching creates, beyond any shadow of doubt, a profound impression, and this impression remains tangible and vigilant throughout the lives of would-be violators, causing them to curb their lust and to pay a fitting regard to the laws of society. It has been urged, as an insurmountable objection to lynching, that many innocent men are put to death by the unreasoning mob, which, carried away by its passions, hangs the first suspicious-looking individual it finds. I have carefully studied the evidence in forty-three lynchings of sexual criminals and have found that the lynchers had, in every case, secured and hung the right man. These forty-three cases have occurred during the last twenty-three years and have been taken indiscriminately from all over the country. I have gathered my information concerning them from the most conservative and level-headed men of the communities in which the lynchings occurred, consequently, can safely assert that my conclusions are based on indisputable facts. Purists condemn the lynching of the sexual criminal, and declare that his lynching is, fundamentally, an illegal act, hence a criminal act. I hold that no act is criminal that benefits society. There is a higher law than the written law of man, the law of the preservation of species, coincidently of civilization. The crime of rape is distinctly atavistic, hence it is a menace to civilization, and should be suppressed no matter how.[1]

HYPERTROPHY OF THE PROSTATE.[2]

By J. T. HAYNES, M.D.,

SURGEON OHIO SOLDIERS' AND SAILORS' HOME, SANDUSKY, O.

Hypertrophy of the prostate gland is a condition which is frequently met with in males who have passed their fifty-fifth year. It is claimed by some authorities that the number of persons thus afflicted, amounts to somewhere about one-third of those living after the specified age has been reached, though it is not implied that all who are affected are necessarily conscious of the change that has taken place. The alteration which takes place in the size of the gland is of the nature of a hypertrophy or overgrowth only. Ashhurst claims that the analogy with ordinary hypertrophies ends here, as, unlike hypertrophy of the bladder or heart, the change in the prostate is apparently purposeless.

In dealing with this subject, it may be well first to dwell for a few moments upon the anatomy of the prostate and the surrounding structures.

The prostate is a gland composed of firm, elastic, and contractile tissue, lying between the bladder and the penis and perforated by the urethra. It is roughly compared to a horse-chestnut in form and dimensions. Its base lies uppermost in contact with the vesical sphincter, while its apex rests against the superior triangular ligament. In the erect posture its long axis is vertical and is about an inch and a quarter in length. Its weight is about the same as that of the testicle, and it has been noted that the active evolution of the two organs begins at the same period, that of puberty, and that the structural and functional development of the one is intimately associated with that of the other during the period of sexual vigor. The organ (according to Gray) is composed of muscular and glandular tissue. The muscular portion represents about three-fourths of the entire mass, and consists of the unstriped fibres principally, all of which is continuous above with the vesicle sphincter, and forming in the upper third of the organ a ring of great firmness and strength. The function of this muscular mass is, in all probability, that of intercepting the backward flow of semen and prostate fluid into the bladder during sexual congress. Below this point the muscle is intermingled with gland-tissue, and near the apex with a quantity of striated fibres. On rectal exploration the apex will be found about an inch and a quarter above the margin of the anus. This gland is also a circular involuntary sphincter to the neck of the bladder. It contains a small utricle (known as sinus pocularis), the male homologue of the uterus, at the mouth of which ejaculatory ducts open. The arteries supplying the prostate arise from the adjacent vesical, hemorrhoidal, and pudic vessels. These vessels are branches of the sciatic, which vessel has its origin in the internal iliac. The prostatic veins receive the dorsal veins of the penis and terminate in the adjacent vesical veins. The nerve supply comes from the hypogastric plexus. It might be added here that the ovarian arteries are the homologues of the spermatic arteries in the male, and correspond in their relation in the upper part of their course.

[1] If purists object, stating that such a law would be unjust and discriminating, I answer, that as long as society considers the violator to be a normal man and treats him as such, just so long will society be guilty of injustice and discrimination toward normal, healthy man. There is a higher and an unwritten law, which, fundamentally, takes precedence of established law; moreover, I do not consider that which redounds to the good of society either barbarous or savage.

[2] Read before the Northern Ohio District Medical Society, March 22, 1895.

As regards the etiology of prostatic hypertrophy but little is known. Injury to the prostatic region is said to have frequently resulted in hypertrophy. The one thing which seems to be essential to the existence of the disease is the advanced age of the patient. Stone of the bladder, stricture of the urethra, irritation by the frequent use of instruments, sedentary habits, gouty or rheumatic diathesis, and exposure to cold and damp have all been cited as predisposing circumstances, but none of these conditions has ever been positively shown to stand in a causative relation to the disease. On the other hand, there is no doubt that, when hypertrophy exists, any of these conditions may greatly aggravate its symptoms. Excesses in drink or in venery, prolonged voluntary retention, etc., are causes of increased prostatic congestion. Harrison in reference to the cause of this affection says, "Assuming that from any cause, such as long retention of urine, habit, position of the body, or the weakness connected with advancing years, the trigone or non-contractile part of the bladder becomes permanently depressed or altered in form, so that the person finds himself unable to get rid of the last half-ounce or so of urine, the effect will be frequently repeated efforts in all the muscles immediately adjacent to a part, which, by reason of its connection and structure, has but little power of expelling." He further states that this will eventually lead to the hypertrophy of the muscular fibres between the orifices of the ureters, the internal uretral bar, as well as to that of the muscular fibres so largely entering into the composition of the prostate. There are other conditions that are given as causative factors, but of the whole list not one can be said to be directly instrumental in bringing about this affection peculiar to man only.

In regard to the treatment of hypertrophy of the prostate, very little was even attempted that proved at all successful, until within the past two years. Hamilton, in speaking of the treatment, claims that it is only palliative at best, and must be conducted with reference solely to the symptoms as they arise. He also advises ten to twenty drops daily of the balsam of copaiba or five to ten drops of the spirits of turpentine. Druitt states that treatment is palliative only. He further states that the chief means of treatment is the catheter, and that by its use the bladder can be kept empty, thus removing what would necessarily prove to be an etiological factor. Harrison employed a similar method, only he tapped from the perineum through the prostate; he says that after this treatment he has seen the hypertrophied gland shrink, and the urine pass again by the urethra. He further states, that on the earliest manifestations of prostatic obstruction, mechanical treatment should be resorted to with the same diligence that is required in the treatment of other forms of urethral obstruction.

Within the past eighteen months the treatment of this condition has indeed turned completely about, and operators have ventured out in an entirely new direction. J. William White, in the *Annals of Surgery* for December, 1893, suggested castration as an advantage in the treatment of these cases, and it is to this departure in the relief of hypertrophy of the prostate that I desire especially to call your attention to-day.

In the *American Medico-Surgical Bulletin* of June 1, 1894, Dr. F. Fremont Smith, of Florida, gives the history of one case, admitted to the St. Augustine Hospital, aged sixty-nine, suffering from hypertrophy of the prostate. Internal treatment and douches were employed for a period of nearly six months. Patient had frequent attacks of acute cystitis which interfered with his sleep and appetite, and his weight was reduced from 165 to 135 pounds. Castration was performed January 17th, no local treatment employed, and on March 1st patient was discharged from hospital. His appetite had returned, his weight had increased to 163 pounds, and there was no longer any retention. He heard from the patient fifteen weeks after the operation that he had had no further trouble.

Again, in the *American Medico-Surgical Bulletin* of November 15, 1894, two cases are given where castration was performed and with marked success. The first case, a man, seventy-one years of age, suffering from hypertrophy of the prostate, with symptoms such as severe and painful desire to urinate, ammoniacal cystitis, rises in temperature, loss of appetite, all of which remained unchanged by palliative means. Castration was performed, both testes removed and wound healed without accident. At the end of two weeks, the prostate was one-third smaller, and in less than three weeks had shrunk to one-third its former size, and in five weeks it was of normal dimensions. Forty days after operation the patient's condition was as follows: Prostate normal in size, the bladder emptied at intervals of four to six hours without resorting to catheter, with no after dribbling. Patient's condition is excellent.

The second case, a man, eighty-one years of age, admitted for retention. Bladder extended to umbilicus. Catheterization impossible and urine withdrawn by suprapubic aspiration. Rectal examination showed prostatic tumor, size of orange. Cystitis became marked and patient's health began to fail. Castration was performed, followed by an almost uninterrupted recovery. From the day after operation the urine came more freely. Ten days after operation the prostate, per rectum, was distinctly smaller, and three weeks after it had practically disappeared; an ordinary silver catheter could be passed with ease.

So far as this form of treatment is concerned, I have had but two cases under my care in which castration was resorted to, and wish to report one of these cases, as it was of especial interest to me.

John G——, aged sixty-three; German; white; a widower; in physique spare; admitted to hospital of Ohio Soldiers' and Sailors' Home, May 24, 1894. Disability; hydrocele of right side, with associated hypertrophy of prostate and tumor of testicle; supposed to be tubercular. Urinalysis normal.

Past History.—Has had great difficulty in voiding urine for a period of more than ten years. Of late years has had to resort to the use of a catheter.

History of Present Disease.—About ten years ago the right side of scrotum became enlarged to the size of a goose-egg. Tumor remained unchanged until about four years back, when it began to increase in size, until it had reached the present dimensions. Has never suffered any pain from the tumor itself, but only inconvenience on account of its enormous size.

Present Condition.—The tumor of the scrotum now the size of fœtal head. By palpation we find slight fluctuation on right side. The left side shows nothing abnormal. No transmitted light.

Treatment.—The left side of the scrotum was tapped and twenty ounces of a semiclear, reddish-brown fluid drawn off. Although great reduction in size of scrotum followed at once, yet the left side remained more than twice the size of the right. An aspirator was attached to cannula and a quantity of stimulating fluid was injected into left side. Patient was then put to bed and an anodyne given.

Result.—The next day the scrotum was swollen to its former size and had become very red and painful. Tension became very great, and on second day the posterior wall of scrotum ruptured. The tissue surrounding the perforation showed positive signs of sloughing. Dressings were changed twice each day and scrotum washed out with bichloride solution.

June 2d.—The sloughing parts were cut away, tunica vaginalis having separated from other portion. The testicle was found in lower and posterior position, and septum very much indurated. Incision enlarged under cocaine to three inches in extent in order to excise remaining sloughs. Temperature, 103.4° F., pulse, 120.

June 11th.—Fever has continued during the entire time, patient becoming weaker each day, and discharge being profuse and very offensive. Consent of patient being obtained, decided to operate at once.

Operation.—No difficulty in administering anæsthetic, which was pure ether. Left scrotum was opened from external abdominal ring to ulcer posteriorly. Membrane dissected from septum and over the entire area including the testicle, to a level with pubic bone. Vitality was undisturbed at this point. Above this site the cord was tied *en masse*; the double ligature with the common hemorrhoidal tie was the mode adopted. The ends of the ligature were brought out and fixed at upper portion of incision. Drainage-tubes introduced and edges united by interrupted sutures.

June 12th.—Says that he feels much better, temperature, 100° F.; pulse quiet, 80 per minute. Feels very weak. Dressings were changed because of oozing. Parts cleansed with bichloride solution. Subsequently dressings changed daily on account of discharge of dark fluid and some pus.

July 1st.—Union of line of incision except at point where ligatures came out, and at point where drainage-tube protrudes. The discharge has almost ceased.

July 5th.—Ligature came away and the wound entirely healed. Patient discharged.

The fourth day after operation the patient told the nurse, that much to his surprise he had been able to pass some urine unassisted by the catheter. This condition gradually increased until the third week after operation, since which time he has not had the slightest difficulty in voiding his urine. He is to day an inmate of the Home, enjoying the best of health and perfectly free from dysuria or any complications resulting from operation. Rectal examination by finger gives a prostate gland much reduced in size, but possibly only atrophied on one side.

I have given this case not to show any result as following the operation other than the effect produced upon the enlarged prostate, and in honesty, I will admit that the atrophy of the prostate was not the point aimed at in the least in making the operation. But I am convinced of the beneficial effect to be derived from this procedure, and deem it, in all cases that will permit, the only course to pursue.

NITROUS OXIDE GAS IN PROLONGED OPERATIONS.

By CHARLES G. PEASE, M.D., D.D.S.,

NEW YORK.

As a substitute for chloroform and ether, in minor and major operations, we have in nitrous oxide gas an anæsthetic not only much safer than the two named, but entirely free from the unpleasant, depressing, and often serious sequelæ.

In ether narcosis the mucous glands secrete profusely, the stomach and fauces are filled with this secretion, and there is laryngeal and bronchial irritation. The cardiac exhilaration during the administration is followed by a corresponding reaction which is decidedly unfavorable to the patient. The ether being eliminated from the blood by and through the skin, lungs, and kidneys, acting as an irritant, tends to increase any inflammatory condition. A tendency to nephritis, plus the administration of ether, is, therefore, a serious matter. Experience has proved this to be only too true.

How many patients have never rallied from an operation under ether? Saturated with the anæsthetic, suffering from nausea, vomiting, sweat, frigidity, shock, the feeble patient is robbed of the vital force necessary to recovery.

With gas there are none of these conditions, and the return to consciousness is usually in less time than half a minute after the removal of the inhaler, and in the experience of the writer, who has administered the gas in many operations, the patient comes out of the narcosis as from a short nap, often joking and laughing, with no depression, or any unpleasant symptoms whatever.

The dangers of chloroform are too well known to be rehearsed here.

As narcosis can be prolonged under gas up to one, two, three, and four hours, with so much greater safety to the patient, and with no unpleasant sequelæ, it must surely come into more general use. The writer admits that he finds it far more tiring to administer gas than to administer the other anæsthetics. But that should have no weight in view of the great advantages to the patient. The cost of gas is also greater, but the patient pays the difference, and is glad to do it.

The writer's portable outfit consists of small cylinders containing one hundred gallons of gas each (condensed) with a convenient case for carrying the same, a gas-bag, tubing, and inhaler, with valves to admit air and shut off gas, and vice versa.

In the event of the failure of heart or lungs to perform their functions, the remedial efforts usually employed in such cases would be indicated, but the writer has never had occasion to resort to such means, as he has had no accidents with gas. Very nervous patients sometimes give a little trouble in that they are not quiet during the narcosis, and require to be held by the assistants.

Gas should never be administered to an alcoholic patient, and alcohol should not be allowed prior to the administration, as the patient is very liable to become disagreeably unmanageable.

In organic lesions of the heart, lungs, and kidneys, gas can be given with comparative safety, when other anæsthetics would be contra-indicated. The extent of the lesion, of course, would modify this statement.

The occasional cyanotic appearance of a patient might alarm a novice, but there is no occasion for anxiety, and the gas need not be pushed to that extent.

101 WEST SEVENTY-SECOND STREET.

How to Take Creosote.—Dr. C. W. Ingraham gives, in the *Medical News*, the following directions: "I give the patient a one-ounce bottle of creosote and an empty eight-ounce bottle. Upon the eight-ounce bottle I place the following label:

"'*Directions:* After putting in the correct number of drops, according to directions on the small bottle, fill with cold water and take the entire contents of the bottle during the day, in equally divided doses, at regular intervals. Make at least six or eight doses. Shake thoroughly each time before taking.'

"Upon the bottle of creosote this label is pasted: 'Put four drops in the eight-ounce bottle, and take according to the directions on that bottle. The second day put in five drops, and the third day put in six drops, etc. Continue to increase one drop per day until twenty-four drops are taken daily. Do not increase beyond twenty-four drops without instructions.'

"One ounce of creosote will last the patient a full month at the beginning, but after the first month two ounces will be taken each month. Creosote in this form may be intrusted to the care of any intelligent adult, and I have never had an accident occur from the method. As the daily amount reaches from twelve to fifteen drops, it will require further dilution. The dose can be emptied into a glass tumbler and a sufficient additional quantity of water quickly added. By this method the patient has a fresh preparation daily, and when taken in this highly diluted aqueous suspension it is wholly non-irritant to the mucous membrane of the mouth, throat, or stomach. When desirable a small amount of some one of the vegetable bitters may be added each morning to the eight-ounce bottle, which will assist in stimulating the appetite."

COMPARATIVE ILLEGITIMACY.

M. PAUL BOURGET, a gentleman dear to the literati for his skill as a novelist and analyzer of those phases of social life which have a dominant sexual trait, has written a book upon America. It has aroused the ire of Mark Twain, who has made a famous retort. M. Bourget had said, in his artistic way, that Americans, when they had any leisure, devoted it to looking up their grandfathers, and Mark Twain to this has replied that the French, when they have any leisure, spent it in hunting up their fathers.

Bourget has become thereby excited and publishes some statistics, which he gets from sources unknown, and which show, as he asserts, that the ratio of illegitimacy is greater in America than in France.

It is upon this point that we desire to make some criticisms ourselves ; for while M. Bourget is assuredly very clever as a verbal artist and portrayer of social complications due to exuberant erotism, he is surely not an expert in demography.

In France the birth-rate has diminished steadily from 26.7 per 1,000 inhabitants in 1872 to 23.04 in 1889, while in the year 1890 the total birth-rate was lower than it had been since 1854.

At the same time the illegitimate births are steadily increasing, and in 1890 amounted to 8.5 per 100 for France and 28.15 per 100 for Paris, whereas in England it is only 4.8 per 1,000 (Bertillon Laquean, *Bull. de la Acadêmie de Médecine*, July, 1892). France has relatively and absolutely more bastards and fewer legal children born now than ten years ago. The ratio of illegitimacy in America, so far as is known, is about the same as that in Great Britain.

The marriage-rate in France is also steadily decreasing, being only 7.1 per 1,000 in 1889, as against 7.69 in 1884. The divorce rate has, on the other hand, steadily increased from 1884, when the divorce law was passed, the rate being 7.0 per 10,000 households in 1890, as against 6.6 in 1884.

The most striking phenomenon after all, however, about the Parisian is, not that he can't find his father (twenty-eight per cent. having none) but that he succeeds in getting born at all, for in this wonderful city, out of every 100 families, 32.3 have no children [1] (unless they are still births). Out of 60,000 babies born in Paris yearly, 20,000 are sent out into the country to nurse, and there thirty-eight per cent. die in the first year. So that if a Parisian is lucky enough to get fathered and then to find the father, he isn't out of his troubles, for he has hardly an even chance of growing up.

In fine, if M. Bourget sets out honestly to make comparisons between the social and moral conditions of Paris or France and America he can hardly fail to see that he is too badly handicapped by statistics to cut a figure pleasing to his national vanity.

[1] Laquean: Loc. cit.

THE SENSATIONS OF THE ANÆSTHETIZED.

DR. GEORGE WYLD describes in *The Lancet* his sensations on being chloroformed. He says : "I suddenly experienced the extraordinary impression that my spiritual being stood visibly outside my body, regarding that deserted body lying on the bed. Shortly afterward I called on three different professional chloroformists and asked them if any of their subjects had ever experienced sensations like my own? In reply one gentleman said, 'I have often heard patients express similar ideas.' Another said, 'I myself have experienced on three occasions, when under chloroform, exactly similar sensations.' And the third gentleman said, 'My patients have often said that they experienced no pain, but felt as if they saw with their inner eye all I was doing during the operations.' I was told of a patient who said after anæsthesia, 'I thought I had got at the bottom of the secrets of nature.' And a dentist told me that many of his patients had experienced similar sensations to those I described."

The late John Addington Symonds described his sensations thus : "I seemed at first in a state of utter blankness ; then came flashes of intense light alternating with blackness, and with a keen vision of what was going on in the room round me, but no sensation of touch. I thought that I was near death, when suddenly my soul became aware of God, who was manifestly dealing with me, handling me, so to speak, in an intense personal present reality. I felt Him streaming in like light upon me and heard Him saying in no language, but as hands touch hands and communicate sensation, 'I led thee ; I guided thee ; you will never sin and weep and wail in madness any more ; for now you have seen Me.' My whole consciousness seemed brought into one point of absolute conviction ; the independence of my mind from my body was proved by the phenomena of this acute sensibility to spiritual facts, this utter deadness of the senses ; Life and Death seemed mere names. . . ." Symonds adds : "I cannot describe the ecstasy I felt," and referring to his experience and its psychological evidence, says, "If this had happened to a man in an uncritical age would it not have carried conviction, like that of Saul of Tarsus, to his soul?"

Dr. Wyld refers to the testimony of others who experienced the feeling that matter was only phenomenal and that the spirit was outside the body. Undoubtedly a psychological study of the experiences of the anæsthetized would furnish interesting results. The feel-

ings are not like those of ordinary intoxication from alcohol or even opium. Hashish, however, sometimes produces similar disturbances. The common and especially unique effect is the disorder of personality, so that the individual feels himself spiritually disembodied and looking at his old material self as a thing apart. It is the best artificial realization of the religious conception of death and the departure of the soul from the body.

STRIPPING THE SEMINAL VESICLES.

Shortly before his recent and untimely death Dr. Bernard E. Vaughan published an article in *The Post-Graduate* entitled "Stripping the Seminal Vesicles for Diagnostic and Therapeutic Purposes." This article opened up a somewhat novel field of procedure and one that promises to be of decided practical value. Four years ago Mr. Jordan Lloyd published an article on the subject of spermato-cystitis in which he concluded :

"1. That spermato-cystitis, although seldom recognized, is not uncommon.

"2. That it is in many ways analogous to salpingitis in women.

"3. That it is usually secondary to urethritis.

"4. That suppuration is exceptional.

"5. That when suppuration occurs, the pus should be liberated by incision made from the perineum.

"6. That it frequently accompanies epididymitis.

"7. That it is frequently diagnosed as an inflammation of the prostate or neck of the bladder.

"8. Diagnosis can be easily made by careful digital examination from the rectum."

Subsequently to this, Dr. E. Fuller published two contributions to the same subject. Despite these articles, however, at the meeting of the American Association of Genito-Urinary Surgeons last June, few of the members present believed that they could diagnose diseases of the seminal vesicles, and some thought it impossible to strip them, as suggested by Dr. Fuller.

Dr. Vaughan reports twenty-eight cases in which he has made examinations and applied treatment for seminal vesiculitis. Six had acute seminal vesiculitis, four double. In two cases he found tuberculosis of the seminal vesicles. In nine cases there was a distended, pouchy condition, associated with a large quantity of seminal fluid containing pus cells and motionless spermatozoa. There were ten cases examined in which the normal seminal vesicles could be distinguished and the contents expelled.

Dr. Vaughan describes the method of examination. The patient, he says, should stand with his back toward the examiner, the legs separated, the body bent at the hips, at an angle of about 70°. The bladder should have been partially emptied, and the abdominal muscles relaxed. The examiner should sit in a chair to the left and behind the patient, and introduce the well-lubricated index-finger of right hand into the rectum, with the other hand over the pubes. With co-operation on the patient's part, in almost every case the prostate, seminal vesicles, and the vasa deferentia can be distinguished. If only for diagnosis, these can be gently palpated, and any change in form or consistency determined. If one wishes to empty the vesicles he does so by a stripping motion.

The method described by Dr. Vaughan has two applications : diagnostic and therapeutical. For diagnosis, the procedure is used—

(1) To decide the question of sterility in the husband before mutilating the wife.

(2) To diagnose suppurative process, as gonorrhœa and tuberculosis, by washing out urinary tract, strip vesicles, and examine microscopically.

The therapeutic application consists in—

(1) Emptying the distended sac where there is obstruction or loss of tone to muscle wall.

(2) Treatment of temporary sterility by emptying the vesicles of old products.

(3) Massage of vesicles to improve muscular tone and increase of blood-supply.

(4) In the treatment of those cases of chronic urethritis dependent on gonorrhœa of the vesicles, which urethritis starts up after coitus or nocturnal emission.

The most striking and apparent use of the stripping process lies in the fact that it will enable the physician to procure the semen of the patient at any time. It is somewhat difficult to understand how the measure can prove of any great therapeutic value, but this point may be left for clinicians to determine.

THE STATE CARE OF THE INSANE OF NEW YORK CITY.

The bill which has been introduced into the New York State Legislature providing for the care by the State (for which read State Political Machine) of the insane of New York City, is certainly liberal enough to the State.

The bill proposes to establish the "Manhattan State Hospital," and to turn over to it the New York City asylums. It provides for a lease to the State of Ward's Island at an annual rental of one dollar, and for a conveyance in fee of all the asylum lands at Central Islip for the same consideration. All the buildings, improvements, equipment, fixtures, furniture, etc., of the asylums go with the land. In other words, the city is to give to the State all its insane asylum property on condition that the State take care of its insane.

It is intended that the State Hospital and all the accommodations for the insane shall be ultimately limited to the two establishments on Ward's Island and at Islip, and to that end it is provided in the same bill that such buildings on Blackwell's and Hart's Islands as are now occupied by the insane shall pass under the control of the managers of the State Hospital until sufficient accommodations shall be provided for their inmates elsewhere, such control not to continue more than five years. Thus, when the plan shall be fully carried out, there will be a complete separation of the insane under State care from the city's institutions of charity and correction, and the buildings of the latter will be free for other uses.

The plan to place all the insane upon one island and the prisoners upon another, thus separating insane and the criminal population, is certainly a wise one, but it might just as easily be done by the city authorities.

As we have before stated, we do not find any promise of improvement in the care of the insane through the proposed measure. The conduct of our State hospitals so far, shows that politics is likely to be just as prominent a factor as it has ever been in our city government. In fact with the aroused public sentiment in this city, we feel much greater confidence in future city than in State administration.

In addition to this there are likely to be practical complications due to the fact that the city pauper insane are all confined for a time in a city hospital.

We believe that it will be for the best interests of the public that the medical profession of this city protest against the proposed change.

We are glad in this connection to note the following editorial admission on the part of the *American Journal of Insanity*. It says: "We have advocated State care for the New York City insane, but if politics and unwarranted, and possibly dictatorial, interference with the local autonomy of the institution are to have sway, there will be little to choose for the unfortunate but helpless insane people who are most concerned, but have least to say."

TRAVELLING AND BRAIN GROWTH.

Dr. Walter Scargill, of Colchester, England, has discovered the remarkable fact that travelling makes the brain grow. He avers and can personally testify that much growth occurs, even to the extent of an inch, at the ages of thirty, forty-five, and sixty! This means of cerebral development he thinks might be applied to idiots, and he suggests that the patients of idiot asylums be shifted about once a year.

Here is a new field perhaps for the ever immanent bicycle. Put the idiot on a wheel and make him travel continually until the size of the hat-band increases from six to seven and a half.

Another suggestion which we modestly put forth is that the Legislative Assembly of this State, that of Kansas, Kentucky, and Massachusetts, swap State Houses every year, thus compelling the statesmen to move over the country, to the benefit of their cerebral convolutions and the improvement of their statesmanship.

News of the Week.

Pneumonia is unusually prevalent in Louisville, the death-rate in the the first quarter of this year being 246.

The Climate of Canada.—In the *Montreal Medical Journal* for March, Professor W. H. Hingston, President of the Montreal Branch of the British Medical Association, discusses the climate of Canada and its effect on the inhabitants of the Dominion. The two chief features in the physical geography of Canada are the profusion of lakes which "moderate the temperature both of summer and winter" and the comparatively low elevation of the land above the sea-level. The atmosphere almost always exhibits a sensible electrical state, and, according to Dr. Hingston, this has much to do with the well-known energy of Canadians. Even the warmest weather in Canada is grateful to the senses, while, on the other hand, the cold is exhilarating and does not affect the human constitution as in countries rendered cold by their great altitude. The death-rate is low, and Canada has no disease that she can call her own. Consumption exists even in that favored clime, but the Canadian climate, from its dryness and equability, is favorable "at certain seasons and under certain circumstances to an arrest of the disease." The conditions of the lung in cases of phthisis which are especially benefited by the Canadian climate are those of imperfect expansion and consolidation. Under the influence of the climate the European loses something of his ruddy color, and his skin becomes dryer and harsher. The effects of the dryness of the air are seen in the dryness of the hair and nails; the hair becomes darker and straighter, partaking more of the aboriginal type; the teeth are said to decay at an earlier age, but this Professor Hingston appears somewhat doubtful about; the fat which gives roundness to the general outline is less abundant, and the muscles of the face or their tendinous prolongations are more prominent. In respect of mental characteristics, while the Canadians do not display the devouring activity of the inhabitants of the States, they are, according to Dr. Hingston, more active than the effete peoples of Europe, occupying in this respect an intermediate position between the Old World and the New. During the two centuries of its existence Canada has given no sign of physical decay. On the contrary, the descendants of the British and German colonists have more than held their own in point of physique, while the children of New France, who have been longest in possession of the soil, are greatly superior in strength and powers of endurance to those of their mother country.

Examining Surgeon for Pension Bureau.—Dr. Arnot Spence of this city has been appointed an Examining Surgeon for the Pension Bureau, vice Coroner Hoeber resigned.

An Old Practitioner.—Dr. Frederick Andros, who died at Minneapolis last week, aged ninety-three, settled at Dubuque, Ia., in 1834, being then the only physician in regular practice west of the Mississippi. He moved to Wisconsin in 1846, accepting a Government appointment as physician to the Winnebago Indians. Dr. Andros was born at Berkeley, Mass., and was graduated at Brown University.

The Malden Hospital, Massachusetts, has just received a gift of $50,000 from Mr. E. S. Converse.

Foreign News Collectors.—Dr. Dujardin-Beaumetz died several months ago. In view of this lamentable fact the following London cablegram is an interesting evidence of the trustworthiness of some of our foreign news collectors. The report reads: "The epidemic in the military hospital at Vitré has been thoroughly investigated, and it has been demonstrated that the prevailing malady is not due to the use of American or other canned meats, as was at first reported. Dr. Dujardin-Beaumetz, an eminent authority, has examined the patients and disproved the theory of the local doctors. He declares that the disease is really spinal cerebral fever, complicated with lockjaw, due to the de-

fective drainage of the place, which induced blood poisoning. The disease is highly contagious. Seventy fatal cases have already resulted."

To Abolish the Present Lunacy Commission.—Senator Lexow has introduced a bill at Albany abolishing the present State Commission in Lunacy, headed by Dr. Carlos F. Macdonald, and creating a commission of five members, each of whom is to receive $5,000 annually.

The Gold "Cure" for Drunkenness.—A telegram from Leavenworth, Kan., says: Judge Myers, of the District Court, has made an important order affecting the rights of Dr. Leslie E. Keeley. W. F. Johnson of Topeka sues Dr. Keeley for $100,000 damages, the petition reciting that the plaintiff has been made a physical wreck because of the gold cure. Judge Myers, in granting the petitioner's request, rules that Dr. Keeley must make known the ingredients of his so-called bichloride of gold compound.

Antitoxin in California.—California is the first State of the Union which has made an appropriation for the manufacture of diphtheria antitoxin. The sum allotted to this purpose is $5,000.

The Loomis Dispensary and Sanitarium for Consumptives.—The officers of this institution have issued an appeal for the support and increase of their plant. They already have a dispensary on West Thirty-fourth Street.

Protest against a Hospital for Contagious Diseases.—Property-owners in the neighborhood of the Yale Infirmary, New Haven, have signed a protest against annexing to it a hospital for students with contagious diseases. They say that such a hospital, for which New York ladies and others have raised about half of the required fund of $10,000, should be put in the outskirts of New Haven, and not, as reported, in one of the best quarters of the city.

Deaths from Small-pox.—A tabulated statement published by the Marine Hospital Bureau gives the number of deaths from small-pox which occurred in each State and Territory of the Union during the year 1894, as well as the number of cases. The deaths were as follows: Arizona, 1; Arkansas, 24; California, 2; Connecticut, 17; District of Columbia, 6; Illinois, 877; Indiana, 10; Kansas, 7; Kentucky, 1; Louisiana, 1; Maine, 1; Massachusetts, 23; Michigan, 84; Minnesota, 4; Missouri, 2; New Jersey, 12; New York, 337; Ohio, 3; Pennsylvania, 34; Rhode Island, 3; Tennessee, 1; Wisconsin, 253. In several States the disease has been more virulent since the beginning of the present year than it ever has been before.

The University Hospital, of Philadelphia, has recently received gifts amounting to nearly sixty thousand dollars.

Way Behind the Times.—A bill has been introduced in the City Council of Baltimore, at the instigation of the Medical and Chirurgical Faculty, to compel physicians to report cases of typhoid fever.

The Tuberculin Test for Tuberculosis in Cattle.—The Report of the Royal Commission on Tuberculosis in Cattle which was recently presented to Parliament, contains some interesting statements about the tuberculin test: The literature of the subject and the results of Professor McFadyean's special inquiry convinces them that extensive tuberculous disease may exist in cattle that appear to all clinical tests to be in perfectly good health. And they are clearly indisposed to believe that a completely trustworthy test of the presence of tuberculosis has yet been proved to exist in the reaction to tuberculin. "Professor McFadyean finds, in his own hands, that this test substance has frequently led to erroneous inferences. He records, as the total outcome of his experiments, that he received wrong indications from tuberculin about the presence or absence of tubercle in cattle in the case of twenty-four animals out of seventy-five; nevertheless, he sums up his report by the statement: 'I have no hesitation in saying that taking full account of its imperfections, tuberculin is the most valuable means of diagnosis in tuberculosis that we possess.' And we understand that, since the time of Professor McFadyean's experiments, the method of using tuberculin as a test has been much improved, and that it is now regarded as affording more trustworthy indications for diagnosis.'

The Retirement of Deputy Surgeon-General Billings.—We learn that Deputy Surgeon-General John S. Billings, of the army, has requested that he be placed on the retired list; and that in October that distinguished officer will leave the Army Medical Museum, of which he is curator, and the Library of the Surgeon-General's Office, of which he is librarian, and these magnificent institutions, that have been made what they are largely by his ability and zeal, will know him no longer. Before the date he has selected for his retirement he hopes to complete his work on the final volume of the Index Catalogue. In seeking official retirement Dr. Billings does not propose to give up work, as he has accepted the chair of hygiene in the University of Pennsylvania.

Danger From Tuberculous Meat.—In regard to this subject, the Royal Commission on Tuberculosis in Cattle give the following recapitulation of their views. "We have obtained ample evidence that food derived from tuberculous animals can produce tuberculosis in healthy animals. The proportion of animals contracting tuberculosis after experimental use of such food is different in one and another class of animals: both carnivora and herbivora are susceptible, and the proportion is high in pigs. In the absence of direct experiments on human subjects we infer that man also can acquire tuberculosis by feeding upon materials derived from tuberculous food animals. The actual amount of tuberculous disease among certain classes of food animals is so large as to afford to man frequent occasions for contracting tuberculous disease through his food As to the proportion of tuberculosis acquired by man through his food or through other means we can form no definite opinion, but we think it probable than an appreciable part of the tuberculosis that affects man is obtained through his food. The circumstances and conditions with regard to the tuberculosis in the food animal which lead to the production of tuberculosis in man are, ultimately, the presence of active tuberculous matter in the food taken from the animal and consumed by the man in a raw or insufficiently cooked state.

Tuberculous disease is observed most frequently in cattle and in swine. It is found far more frequently in cattle (full grown) than in calves, and with much greater frequency in cows kept in town cow-houses than in cattle bred for the express purpose of slaughter. Tuberculous matter is but seldom found in the meat substance of the carcass; it is principally found in the organs, membranes, and glands. There is reason to believe that tuberculous matter, when present in meat sold to the public, is more commonly due to the contamination of the surface of the meat with material derived from other diseased parts than to disease of the meat itself. The same matter is found in the milk of cows when the udder has become invaded by tuberculous disease, and seldom or never when the udder is not diseased. Tuberculous matter in milk is exceptionally active in its operation upon animals fed either with the milk or with dairy produce derived from it. No doubt the largest part of the tuberculosis which man obtains through his food is by means of milk containing tuberculous matter. The recognition of tuberculous disease during the life of an animal is not wholly unattended with difficulty. Happily, however, it can in most cases be detected with certainty in the udders of milch cows. Provided every part that is the seat of tuberculous matter be avoided and destroyed, and provided care be taken to save from contamination by such matter the actual meat substance of a tuberculous animal, a great deal of meat from animals affected by tuberculosis may be eaten without risk to the consumer. Ordinary processes of cooking applied to meat which has got contaminated on its surface are probably sufficient to destroy the harmful quality. They would not avail to render wholesome any piece of meat that contained tuberculous matter in its deeper parts. In regard to milk, we are aware of the preference by English people for drinking cows' milk raw—a practice attended by danger on account of possible contamination by pathogenic organisms. The boiling of milk, even for a moment, would probably be sufficient to remove the very dangerous quality of tuberculous milk.

Obituary.

JOHN W. BYRON, M.D.,

NEW YORK.

Dr. John W. Byron, the distinguished bacteriologist, died May 8th of pulmonary tuberculosis contracted during his investigations of that disease in laboratory work. He was born in Lima, Peru, July 24, 1861, and was taken away during his most active period of usefulness. With a bent toward bacteriological work he became identified with it almost from the commencement of a brilliant career. Shortly after his graduation he removed to Havana, and during a yellow-fever epidemic there he made laborious bacteriological researches, which eventuated in the establishment of certain principles of propagation of the disease which proved to be of the greatest practical utility in staying the progress and mitigating the effects of the direful scourge. After a course of laboratory study in Berlin and Paris he was invited five years ago to accept the position of bacteriologist to the Loomis Laboratory, in which position while experimenting with tubercle bacilli he is said to have developed the symptoms of his fatal malady.

When cholera appeared in New York in 1894, by invitation of Health Officer Jenkins, he assumed charge of the cholera camp at Swinburne Island, where he remained quarantined during all the period of the threatened invasion. With an earnestness of purpose in his work usual with him, he devoted his best work to the interest of the public safety, and as a reward gained for himself the enviable reputation of a public benefactor. The disease of which he died first showed itself in March, 1894, and made very rapid progress, in spite of his determination to fight against it and continue his investigations. Change of climate was of no avail, and bravely hoping against hope, he died, regretted and mourned by the entire community, a sacrifice to science and an ornament to the profession he so ardently loved.

Reviews and Notices.

Health Notes for Young Wives. By Aimée Raymond Schroeder, M.D. New York: William Wood & Co. 1895. 12mo, pp. 210.

The very suggestive title of this little book is more than fulfilled by its contents. The authoress has manifested great tact in dealing intelligently, judiciously, and chastely with a subject that is always a delicate one to handle from a popular standpoint. The information, given in a plain and clear style, is all that is necessary for a young wife to know who wishes to act with intelligence in caring for herself and her prospective offspring. Even the abstruse subjects of ovulation and generation are described in a manner that cannot fail to be understood by an ordinary reader. Many of the little points concerning which the prospective mother is so desirous of knowing are very fully explained, especially those which refer to possible accidents and emergencies which are liable to occur during the gestatory period. The authoress very truly implies that the physician is not expected to enter into all these details, interesting as they may be for the mother, and for that reason she attempts, very successfully, we think, to stand between him and his patient, in quieting her fears, relieving her anxieties, and affording her physical comfort by calling attention in a very general way to the commonsense application of those principles which should be known by every intelligent mother. The care of the infant from the time it is born until it is able to feed itself, claims its share of attention, and will be eagerly read and properly appreciated by the readers. In fact it is such a book as the physician can recommend to his patient and save himself much time and trouble in the giving of information which, under other circumstances, is so necessary and important.

The Medical Annual and Practitioner's Index. A work of Reference for Medical Practitioners, 1895. Thirteenth year. Bristol, Stone Bridge: John Wright & Co.; New York: E. B. Treat.

This book, containing over seven hundred pages, is the outcome of the most recent medical contributions to date. It has the combined efforts of the most prominent members on both sides of the Atlantic, and is rather an international result. Some of the illustrations, for example on page 354—relating to acute œdematous laryngitis, subglottic œdema, acute perichondritis—are excellent.

The many interesting chapters, notably on diseases of the ear and the management of skin diseases, make it especially valuable for the everyday practitioner. The book well deserves careful study and will then only be appreciated.

Society Reports.

American Medical Association.

Forty-sixth Annual Meeting, held in Baltimore, May 7, 8, 9, and 10, 1895.

First Day, Tuesday, May 7th.

The first session of the Forty-sixth Annual Meeting of the Association was held in the Music Hall, on Mount Royal Avenue. It was called to order by the President, Dr. Donald Maclean, of Detroit, at 10.45 A.M. The opening prayer was delivered by Rt. Rev. William Paret, the Episcopal Bishop of Maryland. Governor Brown was to have delivered an address of welcome to the State, but was unable to be present. The members were welcomed to the city by the Hon. F. C. Latrobe, Mayor of Baltimore. He said that though himself a lawyer by profession, he had always entertained great admiration and respect for medical men. Physicians and lawyers were alike sufferers from the gibes and slanders of those who had been restored to health or had been aided in obtaining their rights by the efforts of one or the other, but who for the time being no longer needed the assistance of either. However, the physician had his revenge when the slanderer fell ill, and his revenge was all the sweeter in that it was a return of good for evil. He was glad to see so many ladies with the delegates, for it spoke well for them and for their husbands and fathers. He was a firm believer in men taking their wives along on their journeys; they (the men) were always safer when travelling with their consorts. He felt sure the members of the Association would be pleased with the hospitalities, public and private, of which they would be the recipients during their stay. If any came to the City Hall he would be most glad to welcome them.

Dr. Samuel C. Chew, Chairman of the Reception Committee, then delivered an address of welcome on behalf of the medical profession of Baltimore. Twenty-eight years, he said, had passed since the Association had last met in Baltimore, and many of the members now present were then not yet in the ranks of the profession—some of them doubtless still unborn. Vast changes had taken place in that period. The population of the United States had increased from 35,000,000 to 70,000,000, that of Baltimore from 250,000 to half a million. This city has now become one of the chief centres of medical education in the country, and attracts each year about one thousand students to its schools of medicine. In 1866, when the Association last met in Baltimore, the shock of the Civil War had not been recovered from. Medicine especially suffered from the conflict, for this, like other sciences, flourishes best in times of peace, and shines not when war moves man's passions. Since that time the advances which had been made were great and varied, but the greatest of them, and the one that presaged the greatest good to humanity, was not the specific treatment of disease nor the development of antiseptic surgery — it was rather (referring to this country) the elevation of the standard of medical education. In the education of the future physician lay the possibility of further advances in medicine. The objects of medicine are twofold, the practical and the ideal. The first object of medicine, the material object, is that the people may have life and have it more abundantly; the second, the spiritual object, is the search for truth—pure, enduring truth. It is to the attainment of these objects that the higher medical education will directly lead. Every year more earnest workers will be impelled to enter the ranks of the students of medicine, as they see the possibilities of some scientific work broadening out before them, and these same workers will go forth from the schools better and better equipped for the labors that are before them, whether they strive especially to further the one or the other of the two great objects of medicine, the granting of life or the search for truth. The truest and most cordial welcome that he could extend the members of the Association was the expression of the hope that their deliberations would result in the promotion of these high objects.

Dr. Osler, Vice-Chairman of the Committee of Arrangements, made several announcements, urging upon the members the duty of registering early and reading the programme for the day's entertainments. He said that the guide-book which was gotten up for the benefit of the members, had been hastily printed, and the proofs had not been submitted to all the members of the Committee; had it been, some advertisements which it contained would not have been admitted. He desired to express his own entire disapproval of certain of them.

Living Issues in Medicine.—Dr. Donald Maclean delivered the presidential address, taking for his theme, "A Few Living Issues Affecting the History of Medicine and what Came of Them." He recalled briefly certain questions which in their day received the active and interested attention of thinking people. For some years immediately preceding and immediately following the beginning of his professional life, the attention of science and of medical thought was directed toward that renowned centre of medical and general learning, his own alma mater, Edinburgh. A glance at the names which at that time constituted its medical faculty will explain this. They were Syme, Simpson, John Hughes Bennett, John Goodsir, Robert Christison, Lyon Playfair, Mr., now Sir William Turner, who is the only one still remaining of that brilliant galaxy of teachers and philosophers. Such a faculty could not fail to attract interested attention. While it is well known that at Edinburgh a vast amount of extremely valuable work was, in these days, accomplished in all departments of medical science, still there was, in that far-famed school, one man and one question toward which, from every quarter of the civilized world, eager anticipations were directed. This man was James Young Simpson, and the question was, "The use of chloroform as an anæsthetic." Having caught the essential idea of relieving pain by the inhalation of ethereal vapors, from this country, Simpson, with the energy and courage of his great nature, devoted all his eloquence, ingenuity, and literary acumen to the development and final establishment of the new doctrine. How he succeeded we now know full well.

The influence of the doctrine of descent and Darwin were next alluded to. In 1859 Darwin's work, entitled "The Origin of Species," appeared in London, and as we look back and contemplate the effect of this book we are forced to admit that it constituted a turning-point in the history of science. It appears now as if by its means the spectators were permitted to behold a new and hitherto unimagined and unimaginable view of the long-sought-for secrets of nature, making many things intelligible which, previous to that time, had been wrapped and hidden in that impenetrable and sepulchral vestment, "mystery."

It would be impossible, within the limits of this review, to particularize the luminous influences which have proceeded to every department of science, all of which had their origin in Darwin's great generalization. Foremost among these was one of profound biologic significance affecting all our previous conceptions of heredity. Heredity must always remain a prime factor in the etiology of disease. A correct conception of that in which it consists would appear to be indispensable for the comprehension of pathologic processes. Manifestly, if Darwin's law were true, and if the acquirements of variations by means of natural selection was the cause of modification in the organism, not only must heredity be the cause of permanence in organic

types, but it must also be upon transmission of beneficial variations that racial development is dependent. These conclusions gave rise to a renewed application of the laws of heredity to medical science. Embryology became a matter of deepest significance. Teratology took rank as a science. Reversions in type began to be intelligible, strange growths were no longer viewed with wonder as *luses naturæ*, as sportive attempts of nature to accomplish something strange, but were studied carefully with an eye to their comparative classification.

While alluding to the influence of Darwin, especially through the doctrine of heredity, it would be wrong not to call attention to another sweeping generalization which must profoundly influence medical thought. The theory of heredity propounded by Professor Weissman, of Freiburg, may be said to have arisen out of Darwin's work largely through being negation of some of Darwin's conjectures. Weissman's theory seeks to explain what no doctrine of heredity has hitherto accounted for—how a single microscopic cell can reproduce parental characteristics, and frequently characteristics of grandparents or remote ancestors. Darwin's doctrine of pangenesis was never felt to be entirely satisfactory. Weissman's theory of the "continuity of the germ plasm"—the inference of the practical immortality of the germ plasm, the explanation of variation by means of natural, not acquired selection, and the admission that a man resembles his parents, not because he acquires by transmission these characteristics, but because he as well as they arose out of the same germ plasm; these are conclusions which, if ultimately substantiated, are bound to influence and modify our conception of disease and its processes most profoundly.

The issue next referred to was that which ultimately eventuated in the complete abandonment of blood-letting and the so-called antiphlogistic expedients upon which the profession had so confidently relied.

The rise and development of the new art of gynecology, under the leadership of J. Marion Sims on this side and of Simpson on the other, was then recorded. From very insignificant and unpromising beginnings this science has certainly, as we all know, increased and grown, and, in short, passed through an almost miraculous process of evolution.

In this retrospective view of living issues in medical thought, it would be impossible to overlook the important and inspiring one comprehended under the name of "the cellular pathology." With this page in the history of our science the great name of Virchow will always be inseparably associated, as its founder and greatest advocate. While the doctrine "*Omnis cellula e cellula*" had not explained all the mysteries of pathology, few can admit that the discoveries of Virchow and his school do not stand out as among the most inspiring discoveries of medicine.

Pasteur, Tyndall, Lister; the mention of these three names, familiar wherever the rays of modern civilization have penetrated is, I am sure, all that is necessary for the purpose of introducing here the ever-fresh and all important "living issue" known as the "germ-theory of disease."

It was undoubtedly the inspiration derived from the Darwinian doctrine of the struggle for existence, ultimately securing the survival of the fittest, that gave new significance to the studies which had begun with Pasteur, and whose relation to surgery had been so splendidly demonstrated by Lister in a series of brilliant and conclusive experiments in 1865. If life from its abstract stand-point were a conflict in which the fittest survived, how much more so was the concrete and organic life the scene of a perpetual warfare with those insidious foes the microbes. It is not possible here to trace the growth and development of the new science of bacteriology, which we know has revolutionized the science of surgery, modified the art of surgery, and subverted our deepest, most fundamental pathologic beliefs. So essential has this science become that to-day we regard no young practitioner as thoroughly equipped for surgical work who is not something of an expert bacteriologist. It is out of the study of bacteriology and microbic pathology that modern medicine is slowly but certainly evolving one of her supreme triumphs. Hitherto the immunity to attacks of small-pox conferred by vaccination has been an isolated and incomprehensible fact. Jenner's discovery has been a witness to the value of empiricism in medicine. In harmony with no theory, explained by no logical device, vaccination has by its own inherent virtue proved the value of undiscovered theories. To-day a meaning is given to the word "immunity" such as was never before known. A great hope animates the noblest of professions, that in all the so-called zymotic diseases immunity may eventually be conferred and the most disastrous agencies of human destruction may be deprived of their malignity through the sublime genius of man.

After reviewing the doctrines of immunity, it was said, "if there be one event that can accentuate this meeting in the memory of those who honor it with their presence it will, I firmly believe, be due to the fact that to-day we, as a profession, stand on the threshold of one of the most beneficent discoveries medicine has ever made. A discovery whose consequences will transcend those of any other in the increase of happiness it will ultimately bring to mankind."

An appeal was made for a remodelling in methods of medical education, and the support of the profession was asked in securing a bureau of health (with an official head in the cabinet). The party, professional or political, which shall succeed in consummating this wise measure will assuredly earn for itself the gratitude and applause of an appreciative nation. The individual citizen who shall materially contribute to the success of this noble "useful plan" will be justified in congratulating himself on having realized the lofty aspiration of the patriot, as well as the sublime and pathetic "wish" of the poet: "*Homines deos accedunt hominibus dando salutem.*"

A vote of thanks was offered upon the conclusion of the address, and it was requested that that part of it which dealt with the question of the establishment of a National Department of Public Health be brought to the particular attention of the Government at Washington.

Report of the Judicial Council.—The report of the Judicial Council upon the question of advertisements in the *Journal* was then presented. The Council found that some objectionable advertisements had been admitted into the *Journal*, and they had called the attention of the Trustees and of the Editor to the fact.

It was then moved that the report of the Trustees be made on Wednesday, and be at once referred to a committee which should make its report on the following day. This motion was vigorously opposed, and a substitute was proposed that a committee be appointed to confer with the Trustees before the latter should make their report. The motions were laid on the table.

It was moved that the Genito-Urinary and Dermatological Sections be united, and the question was referred to the respective Sections for consideration and action.

To Raise the Rank of Assistant Surgeons in the Navy.—Dr. Millard, of St. Paul, introduced a resolution to present a memorial to the Senate Committee on Naval Affairs praying that the officers of the medical corps of the navy may have the same rank, pay, and emoluments as are now enjoyed by officers of the medical corps of the army. Owing to the unjust treatment of young medical officers in the navy, that branch of the service was suffering, and it was impossible to get young men with the necessary high standard of medical ability and physical health to come up for examination and then submit to the indignities at present put

upon junior medical officers in the navy. It was moved and carried that this resolution be printed and that a copy be sent to the President of the United States, the Secretary of the Navy, and every member of the 54th Congress.

Advertisements in the Journal.—Dr. Leartus Connor, of Detroit, moved that a committee be appointed to determine what proportion of the members of the Association are accustomed to use proprietary remedies in their practice, and that, if it should be found that a majority did prescribe these drugs, all objection to the printing of advertisements in the *Journal* be withdrawn.

This motion, like all the preceding which had touched upon the question, was at once laid upon the table.

The general session was then adjourned.

Second Day, Wednesday, May 8th.

The meeting was called to order by the President at 10.30 A.M. It was announced that a delegation from the American Pharmaceutical Association was present and the courtesies of the American Medical Association were extended to it. The chairman of the delegation was invited to a seat on the platform. The Nominating Committee was then appointed.

Successful Appeal for the Rush Monument.—Dr. Albert L. Gihon, U. S. Navy, then presented the report of the Rush Monument Committee. He said that he had regretfully to report that the amount thus far collected for this most worthy object was only $3,094.39. It was a subject of reproach to the American Medical Association that the necessary amount for a monument to Rush could not be raised, while in a much shorter time the American Surgical Association had collected all that was needed for a monument to Gross. Dr. Gihon then sketched briefly the life of Benjamin Rush, recounting all that he had done for science and for the glory of American medicine. He died at the age of sixty-eight, from the typhus which was then epidemic in Philadelphia, and which he was battling against with all his energy. The speaker said that he could guarantee that the pedestal for the monument would be furnished free of cost to the Association, a beautiful and most commanding site was already selected, and all that was now needed was that the Association raise the money for the statue. The appeal was most eloquent, and bore fruit as no previous one had done. A number of those present offered to give personally, or to be responsible for the raising of, sums varying from $50 to $500, and before the next business came before the Association, the funds of the Monument Committee had been increased by over $2,000.

On motion, the thanks of the Association were extended to Dr. Gihon for his unremitting labors on the Rush Monument Committee, and the report of the Committee was accepted and ordered to be published. It was also moved that each delegate of the Association be constituted a special committee of one to solicit subscriptions from the members of his local society and to transmit them to the treasurer of the National Committee at Washington.

Reports of Officers and Committees.—The reports of the Secretary and of the Treasurer were read and accepted. Letters were read from the Mayor of Hot Springs, and from the President of the Hot Springs Medical Society inviting the Association to hold its next annual meeting in that city. The Committee on General Business reported adversely on the proposed establishment of a separate section on orthopedic surgery.

Department of Public Health.—The Secretary read a communication from the Section on State Medicine containing suggestions relative to the establishment of a National Health Department, and calling for the appropriation of a sum sufficient to meet the necessary expenses of bringing the matter before Congress. The communication was referred to the Trustees.

Wicked Cleveland Doctors.—A communication was read from a member protesting against the admission to the Association of any member of the Cleveland Medical Society on the ground that certain members of the Society had violated the Code of Ethics by meeting irregular practitioners in consultation. The protest, which was couched in vigorous terms, was referred, without any discussion, to the Judicial Council.

Four Years' Course of Study.—Dr. Wilson, of Columbus, O., offered a resolution urging the Association of American Medical Colleges not to rescind the rule of a four years' course of study which was adopted at the last meeting, and deprecating efforts which were being made to reduce this limit of study to three years. The resolution was unanimously adopted.

The Malarial Disorders of Large Cities, with Especial Reference to Chicago, was the title of an address by William E. Quine, M.D., of Chicago, Ill. It is a fact of familiar observation and comment that irregular cases of malarial disorder are occasionally met with at all seasons of the year and in all localities. It is equally well known that the conditions existing in large cities are inimical to the production of the malarial poison. The busiest metropolitan physician sees very few examples of frank periodical malarial fever that unquestionably originated in paved and sewered portions of his city. The rare cases that do occur are accounted for upon the assumption of "limited foci of infection." If an excavation for building purposes is found in the neighborhood, no matter what the season of the year, it is readily assumed that the upturning of the soil is the cause of the patient's sickness. Or, if the individual have been out of the city, at any time within a period of a year or two, it is taken for granted with equal promptitude and with equal lack of knowledge of the truth, that he received the infection at that time, and that it has been sleeping or "latent" in his body ever since; and if he actually visited a region known to be malarious, even though it were several years before, the discovery of the fact is regarded as having almost the force of a demonstration of the time and place of intoxication. And if no recent excavation can be found and no absence from the city have occurred, it is nevertheless heroically maintained that some subtle emanation from the soil, somewhere, must be held responsible for the result. In considering this problem it is well to include the questions of season, climate, and locality. Contemplate the climate of Chicago between November and March, when the earth is frozen to a depth of a foot or more a good part of the time, and also covered with frozen snow, to say nothing of macadamized pavement; when the temperature has been below zero for a month and below the freezing point for several months; when building operations are arrested and a recent excavation cannot be found anywhere; and then try to account for the malarial affections that prevail on the finest avenues and boulevards of that city during and between the months named, by assuming that there has been some subtle morbific emanation from the soil. The country surrounding the head of Lake Michigan was intensely miasmatic before it became densely populated and comparatively well drained; and the environs of Chicago are miasmatic still. They drain into Lake Michigan. Modern treatises say that the prevalence of malarial disorders in the region of the Great Lakes is not extensive, but is limited in great part to the vicinity of Lake St. Clair and the southern shore of Lake Erie. Dr. Quine has been teaching medical students for many years that there were no paludal diseases in Chicago that originated in finished portions of the city, except here and there a chance case resulting from fresh upturnings of the soil. He believed that to be true till a couple of months ago. He used to think that malarial infection

was easily recognizable, except in rare instances, on the basis of a strong individuality of its symptomatology; but now he thinks that cases are common in which no man that lives, or ever has lived, can make a reliable diagnosis on the basis of their external phenomena. He also thinks that he has been seeing such cases all his life and labelling them "irregular typhoid fever" and "rheumatism" and "grippe" and "purpurpa hemorrhagica," or something else. He used to refer to the word "malaria" as the refuge of ignorance, and it was and is and will continue to be used by doctors when they do not know what is the matter with their patients. But when the diagnosis is supported by a microscopical demonstration it is different. We can ridicule an opinion, but we must make obeisance to a fact. In this day diagnosis is not always a mere matter of judgment. It may be a matter of demonstration. For purposes of medical literature and debate there are no cases of malarial disease in large cities and other non-malarious localities except such as have been proved by microscopical examination of the blood. And yet just such cases are common in Chicago; and, if they are common in Chicago, it would be surprising if they did not occur at all in Milwaukee and Detroit and Cleveland and Buffalo.

It is interesting to recall the fact, set forth in Parkes' Treatise on Hygiene, that the inhabitants of the highly malarious Plains of Troy, and of the extensive and pestilential marshy regions of India, are unanimous in testifying that those who drink marshy water are liable to have fevers at all times of the year, and that those who studiously avoid the use of such water are affected, if at all, only during the late summer and autumn months. It is also serviceable to remember that places inherently healthful are dangerous to life by reason of their connection with the breeding places of malaria through rivers which constitute the sources of water supply for their inhabitants. Aitken points out that the Upper Godavery Tract, one of the most virulently malarious regions of India, does not contain one acre of marshy ground; but its people drink the water of the Godavery River, which drains more dense forest land than any river in the Empire. Similar illustrations might be gathered from various parts of our own country. Professor Bemiss, of New Orleans, shows that the poison of malaria may live in water an indefinite and undetermined time and be conveyed by water-currents through immense distances, even to remote islands and continents. If these statements are true we may use the facts upon which they are based in elucidating the causes of the prevalence of palustral diseases in Chicago and, possibly, in the other lake cities named. Many a marshy stream empties its waters into those of Lake Michigan. The prevailing current of the lake is northward toward the Straits of Mackinaw. The Calumet River, which drains an extensive marshy area in the northwestern part of Indiana and the adjoining portion of Illinois, empties its accumulations of organic matter into the lake three or four miles south of the "Crib," or opening of the great tunnel which supplies the south division of the city with water. The Chicago River also drains a marshy region, and its polluted waters passing into the lake and directed northward, away from the tunnel opening just alluded to, are more likely to affect the sources of supply of other portions of the city. Contrary winds, doubtless, disturb the ordinary direction of diffusion of the marsh poisons through the lake. It is not to be inferred that the water used by the citizens of Chicago is inferior to that of other large cities, for there is abundant evidence that it is not; but it cannot be denied that it contains the products of the marshy regions surrounding the head of Lake Michigan. Nor is it to be assumed that every drop, nor even every tun of this water is thus contaminated. It will be sufficient to admit that here and there a citizen gets a dose of the poison in his drink. This is to him a more rational and satisfying explanation of the midwinter origination of malarial disorders in Chicago, and, possibly, in other lake cities, than any supposition in favor of limited foci of infection which requires us to believe that frozen ground covered with frozen snow can belch forth miasm into an atmosphere whose temperature is below zero and stock that atmosphere with living malarial organisms.

Dr. Quine then gave the clinical records of a number of extremely interesting cases showing difficulties in diagnosis and the occasional inutility of treatment, which represented in the main the observations of Dr. Frank Seward Johnson, Dr. Frank Billings, and himself, and covered a period of several months.

Blood examinations were made only in confusing and suspicious cases, and many instances of malarial infection may have been overlooked. The exact source of infection in such cases is a matter of conjecture. There may be those who can conceive of protozoa disporting themselves on the lake shore in December or January without a stitch of clothes on, in an atmosphere that is ten degrees below zero; but it is easier to believe that the malarial organisms, like other protozoa, live in the water and gain entrance to the human body by being swallowed. This is not intended as a denial of the possibility, nor even of the likelihood, that marsh air may be laden with them, especially the night and early morning air containing an abundance of moisture. So far as known every vital phenomenon manifested by these parasites requires the presence of water. But it is obvious that the very word malaria—bad air—prejudges the case and tends to prevent a fair investigation of contradictory facts. The proofs of water infection are quite as strong as those of air infection, and there is not a doubt that impure water is responsible for the occurrence of malarial derangements with immensely greater frequency than is generally known. There is good reason to suspect that marsh poison is a more common cause of death in large cities than has been supposed, and that the "masked" or atypical forms of morbid action are rarely identified. Most of the cases met with have been of the "masked" variety, and, from the standpoint of external phenomena, have not been recognizable as examples of malarial infection. Some of the cases have been easily diagnosed on the basis of the periodicity of their symptoms, neuralgic or febrile. In some pulmonary tuberculosis and malarial toxæmia coexisted—an impressive fact, suggesting the idea that the diminished powers of resistance occasioned by one, predisposes to the other. In, perhaps, half the cases a history of periodicity may be elicited, but it generally requires close questioning and observation to do so. The absence or presence of this feature is not safe ground for differential diagnosis. Distinction must be made between true periodicity and erratic appearance and disappearance of symptoms or of fluctuations in their severity. The entire absence of fever would be enough to obviate suspicion on the part of city doctors, especially in the winter season of northern latitudes, that the case in hand might be one of paludal intoxication. The failure of quinine to arrest febrile or other symptoms of disease is considered by many a demonstration that such disease is non-malarial. This assumption is not correct. A patient whose blood is teeming with hematozoa may be profoundly cinchonized for weeks and then die with an undiminished number of parasites in his circulation. In other cases the medicine is instantly efficacious. Under the use of quinine some symptoms disappear and others persist.

Some pointed questions can be asked as to the soundness of prevailing opinions concerning the incubative period of these disorders. The duration of this period, as stated by authoritative writers, varies between a few minutes and several years. If the meaning of the term is limited to the time intervening between the reception of the hematozoon and the outbreak of a periodical fever, the indefiniteness of statement referred to is fully warranted; for, inasmuch

as no outbreak of fever may occur at all, the patient may die while the germ is still sluggishly incubating. That is, the infection may kill without causing any important elevation of temperature.

The same considerations must be applied to the elucidation of the question of relapses. In recurrent true malarial fevers it may not be easy to differentiate between relapses and new infections; but we may investigate and eventually be able to answer the question. Suppose a citizen of Chicago had an attack of ague or pneumonia or typhoid fever, recovered, remained in perfect health a year, and then had another attack; is this relapse? The affirmative would represent prevailing opinion in relation to a malarial fever; but is there any proof that prevailing opinion is correct? If by the term "relapse" is meant repeated outbreaks of fever during the course of continuous infection—the patient being sick with other derangements caused by the infection every day of the time—the meaning is different from that given to it in relation to other kinds of disease. It is obvious that all our literature on the etiology of malarial diseases must be revised and put in accord with existing facts.

The fact that the germs of malaria are often conveyed into the body by other media than the air—media that we can easily sterilize before permitting them to enter the body—is one of the greatest facts of the day. It makes the duty of the doctor plain. We grow enthusiastic in contemplating the possibilities of the antitoxins, with which we hope to throttle infection the instant it invades the human sanctuary. But, after all, prevention is a still higher aim, and it is the chief glory of our profession that its best minds and purest hearts are ceaselessly active in this direction.

A vote of thanks to Dr. Quine for his interesting address was passed, and the morning session was then adjourned.

Third Day, Thursday, May 9th.

The meeting was called to order by the President at 10.30 A.M.

The report of the judicial council was presented. The protests against the registration of certain gentlemen from Pennsylvania and Ohio were referred to the respective State Societies. The report of the trustees was then read. The report said that hereafter no advertisements of medical preparations would be accepted for the *Journal* unless the makers published at the same time the formulæ of such preparations. On motion the report was unanimously approved.

Address on Surgery.—Dr. C. A. Wheaton, of St. Paul, then read the address on surgery. The speaker said the specialist should be better prepared, and a surgeon should be learned in all branches, and should practise general medicine for a time. He regretted the decline of the family physician, who was formerly the oracle consulted on all subjects, and whose advice was taken on many matters other than medical. A review of surgery since the introduction of anæsthesia and antisepsis is indeed a wonderful story, but it is not all as it should be, and the modern surgeon often abuses Nature's resources. The speaker then passed in rapid review the surgery of special regions in both sexes. He hailed the growth of conservatism in the surgery of the female pelvic organs. Man's pelvic extremity is now perhaps in greater danger than woman's. Whether the new suggestion for the cure of the enlarged prostate will find general approval, especially of the patients, is very doubtful. There is a danger that joint surgery may become too mechanical, but in other branches of orthopedic surgery the knife is in great measure taking the place of mechanical apparatus.

A Permanent Home.—A resolution was immatured to raise the dues to $6, the extra dollar to be applied to the formation of a building fund. Referred to the Business Committee. No amendments were allowed. On motion all the pending amendments to the constitution and by-laws were indefinitely postponed. The proposed amendment to the Code of Ethics, striking out the clause forbidding the patenting of surgical instruments, was likewise indefinitely postponed. The report of the Committee on Department of Public Health was then presented.

Election of Officers.—The Nominating Committee recommended the following for election: *President*, Beverly Cole, of California; *Vice-presidents*, Dr. Chisholm, of Maryland, Lagrange, of Texas, Clarke, of Mississippi, and Satterwhite, of Virginia; *Secretary*, Dr. Woodbury, of Philadelphia, Pa.; *Treasurer*, Dr. H. P. Newman, of Chicago, Ill.; *Address on Medicine* by Dr. Osler, of Baltimore, Md.; *Address on Surgery* by Dr. Senn, of Chicago, Ill.; *Address on State Medicine* by Dr. Rohé, of Baltimore, Md.

The session then adjourned. The next meeting will be held at Atlanta, Ga., the first Tuesday in May, 1896.

Section in Medicine.

First Day, Tuesday, May 7th.

Chairman's Address.—Dr. E. W. Kellogg, of Milwaukee, said that it was with peculiar fitness that we meet this year in Baltimore, where nearly half a century ago this Association gave its birth-cry. It has outgrown its infancy, passed successfully through adolescence, and is now in a vigorous maturity. The development of medical science has led to the formation of new sections, and thus slice after slice has been taken from the territory formerly occupied by the Section in Medicine. Nevertheless, our growth as a Section, while not so marked perhaps as that in surgery and gynecology, is yet apparent.

Some idea of the progress of these last forty-seven years can be obtained by reading from the Report of the Committee on Medical Sciences, which said to the Association in its natal year that "there is confident reason to believe that there are certain ethereal vapors which when inhaled will produce profound insensibility, and that in this state operations on any part of the human body can be performed without the least pain to, or consciousness of, the patient." Anæsthesia, the greatest blessing ever vouchsafed to man, was then being introduced. Yet so great was the scepticism of that day to its utility that the committee were divided in their opinion as to its practicability. Quinine was coming to be regarded as a specific for malarial disorders, though the etiology of the latter was unknown. The salicylates and antipyretics were as yet unintroduced to medical practice.

In 1877 the germ-theory of disease was first introduced. It is seductive, but has led to many unwarrantable deductions. Of the more recent so-called advances many are more apparent than real. Our people are prone to follow fads, and even the medical profession is not exempt from this tendency. The temple of medicine builds but slowly, and many stones laid in the first flush of a fancied new discovery have had to be removed by the calmer judgment of subsequent clinical experience. Time and experience alone can demonstrate the soundness of our workmanship. Antisepsis has gone forward with a mighty sweep, but it seems to have reached its high-water mark and already the top crest of the wave is scattering into foam. We are learning that it is better to avoid the causes of disease than to remove their effects, and that good hygiene is preferable to therapeutics. During the past year the question of serum therapy has become of transcendent importance. It is either a tremendous farce or else the greatest advance in the battle against physical ills since Jenner's immortal victory. The serum must be pure, the diagnosis of our cases must be a bacteriological one, the injections must be made under antiseptic precautions, and the treatment begun at the earliest possi-

ble moment. If even one-half of what is claimed for the remedy be true, it is well worthy of a further trial. But the claims of its advocates are met by the assertions of its opponents as to its uselessness in secondary infections of the bronchi, and its deleterious effects on joints, kidneys, and skin. Lesions even fatal have followed its use. One year's experience is not sufficient to determine its value, and we must look upon the remedy as still *sub judice* and use it somewhat empirically.

In these days of the rapid diffusion of knowledge the fame of panaceas of all sorts is quickly heralded from one part of the world to another, but we cannot always be certain whether the light on the horizon is a sign of dawn or merely a will-o'-the-wisp to lead us into realms of still greater uncertainty. Our experience with tuberculin and the knowledge that many cases (as in diphtheria) recover should alike make us doubly cautious at the present juncture.

A hopeful sign of the times is seen in the present reaction against the use of the heart-depressing antipyretics except in extraordinary cases. Their abuse upon their introduction was beyond all reason, and it is a matter for congratulation that a reaction in this respect has already begun.

Another important matter is the necessity of urging upon the public the acceptance of the contagious nature of tuberculosis. As long as travellers go up and down our land scattering its germs, just so long will it continue to ravage our population. Public ignorance upon this point must be enlightened by the missionary work of the medical profession, and the enactment of proper laws upon this subject be required.

New Departures in Therapeutics.—Dr. John H. Hollister, of Chicago, read a paper with this title. In order to judge of the medical theories of any age, he said, it is only necessary to study the therapeutics of that age. For many years medical science was compelled to conduct a defensive warfare as we were ignorant of the etiology of morbid processes and were compelled to exhibit our remedies empirically; but the microscope and laboratory have opened up to us fields of great promise, and we now feel the impress of a new era from which will date the renaissance of medicine. The therapy of to-day is aggressive. Twenty years ago the two great therapeutic theories were, first, the cellular, and second, the humoral. At this later day we have, in a sense, made a return to these landmarks, and can now speak of organic therapy, or the therapy of substitution, and of the sero-therapy. The former was ably championed by Virchow, and with the latter the name of Behring is inseparably linked. The organic therapy is based upon the fact that all vital activity has a cellular genesis, and that an equilibrium of all these activities constitutes that condition which we call perfect health. Whenever there is an impairment of cell activity we have impaired function, cell degeneration, and in the worst cases, death. Remedial agents are valuable as they affect cell vitality. Cells have a certain *vis vitæ*, or resistance against morbid processes. They elaborate nucleins, proteids, and albuminoids, which oppose the influence of toxic products. Slight cell-irritation increases cell activity. And in their struggle with bacteria they act not as phagocytes, but throw themselves around the invader so as to surround him with more antitoxin. Cells are supposed to have a selective power of absorption. Hence have arisen a series of nutritive extracts made from various organs. The theory of Brown-Séquard, which was so much ridiculed at first, has now become better understood and followed out in a logical way. With two substances of this latter group the writer has had some practical experience. He has used red bone-marrow for the past two years for simple anæmia, and has seen better results therefrom than previously with arsenic, oil, or iron. He has also used nuclein, though the discovery of this is not a new thing. Vaughan has already shown that there are certain substances which can be extracted from animal tissues, notably the thyroid, spleen, and bone-marrow, which, when injected into the animal economy seem to have an antiseptic power in the alimentary canal, stimulate the brain and nerves, and energize all vital processes. Nuclein seems antidotal to diphtheria, and the cell reaction which is originated by its use increases the nuclein supply of the body.

As to sero-therapy, it is a logical outcome of the germ-theory of disease, which itself grew out of the discovery of cell agency in fermentation, the discovery of living organisms in pus, the conveyance of germs through the air, and their appearance in the blood and tissues; then followed culture-work, and, finally, the causative relation of specific microbes to specific diseases. Finally came up the principle of systemic infection from germ-growth over and above the local effect of their ravages. To oppose this physiologically came the discovery of the germicidal power of blood-serum and the establishment of the doctrines of artificial immunization, first proven with respect to anthrax, and now with reference to several other maladies. Important points to decide are the dosage of the serum to be injected, and the fact as to its permanency in our armamentarium.

In the opinion of our German *confrères* its introduction in diphtheria has reduced the mortality from forty-four per cent. to twenty-one per cent. One observer, out of five hundred and twenty-five cases had a mortality of only eighteen per cent., though before the serum injections it had been twenty-one per cent. At the recent Medical Congress in Munich it was declared to be the sense of the meeting, first, that it is harmless; second, that many observers have seen good results from its use, and third, that as to its prophylactic power, the question is still open.

Several points yet remain unsettled. We do not yet know enough as to the possible globicidal power of the transferred serum to say whether the remedy is perfectly safe. Nor are we well acquainted with the effects and counter-effects of mixed infections. But if infectious diseases are developed by micro-organisms, and if blood-serum is injurious, other means of therapeutic value may yet be found. Edinger, of Freiburg, has noted that the mucous secretions and saliva are distinctly antiseptic and that both contain a large relative percentage of thiocyanate of potassium. He has combined this substance with quinoline and produced a compound called rhodonate of methyl-pyridine. Solutions of this check the growth of Loeffler bacilli in one hour (1 to 1,000) and that of staphyloccus aureus (3 to 200) in the same time. It is not caustic, as carbolic acid, nor poisonous, as bichloride of mercury.

The discussion on this paper was opened by Dr. W. C. Quine, of Chicago. He had used the extract of bone marrow and could give his unequivocal endorsement as to its value in simple anæmia and in cases of apparent progressive pernicious anæmia. In a case of splenic leucæmia, it had increased the hæmoglobin eight per cent. and the red cells seventeen per cent. Yet notwithstanding this the multiplication of white cells went on with even greater rapidity than before. So that there was a great increase in the volume of the blood by reason of the augmentation of its cellular contents.

In the use of the diphtheria antitoxin, he had seen various eruptions, and in one case, bloody albuminuria, the case, however, recovering. But he had also had some very striking recoveries in cases where laryngeal or nasal involvements were threatened, and it appeared that death would result in a day or two without injections were made. Relief in a few such cases had led him to cherish a distinct regard for the new remedy; nevertheless, it was a gift horse whose merits needed the closest inspection.

Dr. F. B. Turck, of Chicago, had seen good results

follow the use of nuclein in the auto-intoxication which results from gastric disorders. This might show itself as a nervous irritability (neurasthenia so-called) or in a soporific depression leading up to melancholia. The toxines from germ growth are upon the intestinal walls, and the use of nuclein has seemed to get directly at the cause of the trouble. Especially good effects have been seen in vasomotor excitation ("flashes," etc.) and in patients with agoraphobia. The substance is not a specific, but is a great addition to our therapeutic resources.

The Physiological Action and Therapy of Calomel in Gastro-Intestinal Disorders.—Dr. W. Blair Stewart, of Atlantic City, N. J., read a paper with this title, based upon a study of the drug in 144 cases. Much of the calomel we use, he said, is impure. Large doses frequently cause griping and pain. This may be due to the adulteration of the remedy, its improper purification, or atmospheric changes. The mercuric bichloride is the most common abnormal ingredient, varying in quantity from a trace to large amounts. Even fatal cases have resulted from calomel administration. Other abnormal ingredients are barium, calcium and lead, which lessen the action of the calomel and may even render it absolutely inert. The remedy should never be administered in connection with acids or chlorides, nor should it be given while gastric digestion is going on, owing to the danger of bichloride formation. It is heavy and slow of assimilation, owing to its non-solubility, the large size of its individual crystals, and the small area of distribution over the alimentary tract.

The calomel we use, therefore, should always be carefully tested. The familiar ammonia test will reveal a strength of one part in one thousand, but the especial thing to do is to triturate the calomel finely with milk sugar. Thereby are the crystals much smaller and the area of distribution is greatly increased. A simple mixture is useless. Trituration must be insisted upon.

The writer is in the habit of using the remedy thus prepared in doses of one-tenth of a grain every hour or half hour until one grain is taken or until evacuation follows. If necessary an ounce of the magnesium citrate solution can be given the next morning. The combination of calomel with soda prevents bichloride formation and favors the alkaline absorption necessary for the absorption of the remedy. He has never observed any diuretic effects *per se*. It may be indirectly diuretic by its general stimulating effect on all the emunctories. In a case of scarlatinal nephritis and in one of mitral dropsy no increase in the urine was noted from its use, though both cases did well on the usual alkaline diuretics, and in one hundred cases in children no diuretic influence of calomel could be discerned.

It is believed that calomel increases the flow of bile by its directly stimulating effect on the liver cells. In diarrhœas it is partly absorbed and partly may have a local antiseptic action. It neutralizes toxines and prevents germ growth. It increases peristalsis and brings about all the good effects which come from flushing the duodenum with nature's cathartic and antiseptic bile.

In adults, Dr. Stewart combines one grain of calomel with one half grain of podophyllum, divides into twelve powders and gives one every two hours. From two to six powders will usually cure the diarrhœa of improper food. Astringents are carefully avoided. In children, so small doses as one one-hundredth (triturated) combined with a minute dose of powdered ipecac will accomplish marvellous results. Good results in the dysentery of adults and in the flux of typhoid are also witnessed. Occasionally sulpho-carbolate of zinc will succeed where calomel fails. In twenty cases of diarrhœa from alcoholism, one-fiftieth calomel with one half this quantity of podophyllum every three or four hours has given the greatest satisfaction.

The discussion was opened by Dr. Chatwell, of Iowa, who asked if the essayist regarded the small doses of calomel as germicidal.

Dr. Steuart replied that he did not, in the strict meaning of the word. Calomel acts by direct stimulation of the liver cells.

Dr. H. D. Didama, of Syracuse, asked if these small doses of calomel are not converted into bichloride, and is not their efficacy due to this fact? If so, large doses of calomel should be more stimulating than small ones.

Dr. H. A. Hare, of Philadelphia, said that it was now proven that calomel was not converted into bichloride in the stomach. This is the chemical truth, though clinical experience would seem to demonstrate otherwise. Calomel is a purgative, while the bichloride is a true cholagogue. Under the influence of the intestinal juices, the former is probably converted (a portion of it) into the gray oxide. As to contamination, examination by a Philadelphia chemist of various tablet triturates and powders on the market had not shown any bichloride contamination; but with triturates combined with the bicarbonate of soda, there was some of the gray oxide.

Dr. Steuart, in closing the discussion, declared that in our laboratory reactions with glass vessels and fixed reagents, we did not exactly reproduce the conditions of the human organism. As to calomel being or not being a cholagogue, the answer was that when we exhibit it we get bilious stools. We don't really know just which chloride starts up the bile flow. As to contamination with bichloride, his experience differed from that of the chemist, for he had found the corrosive preparation in calomel.

Treatment of Asiatic Cholera.—Dr. Elmer Lee, of Chicago, read the paper. After giving a description of the classical features of the disease, he alluded to some of the drugs of reputed value in its treatment. Calomel, salol, and quinine have all proven broken reeds. Iodine as a per-iodate is useless. Uretin for the kidneys and digitalis for the heart are at the best only adjuvants. In the last epidemic at Hamburg, water acidulated with hydrochloric and sulphuric acids was given freely as a drink. Hypodermoclysis of one-half per cent. normal salt solution kept up the volume of the blood and so fulfilled one indication. The great problem was how to remove the toxines in the shortest possible space of time. Ten years ago Ferrán, of Valencia, had introduced inoculation for the disease. Haffkin had followed him, but the results of both were worse than useless. The true remedy is undoubtedly in the abundant use of pure water, both by the mouth and by rectal injection. It should be given warm, and though a little be vomited its use should be persevered in. We cannot use too much. The colon should be flushed four times daily, and from one to ten quarts given by the mouth. Diet must not be neglected, and the body heat must be kept up. Dr. Lee also exhibited a new variety of fountain syringe.

Dr. John H. Hollister discussed the paper, stating that he had passed through four cholera seasons and had found the two most useful remedies to be large injections of tannic acid in water and the free use of cinnamon infusion by the mouth. Neither remedy is, however, experimentally germicidal on the cholera bacillus. Cinnamon water was also useful in the irritability of the intestinal canal in children in summer diarrhœa.

SECTION ON SURGERY.

First Day, Tuesday, May 7th.

The Section on Surgery was called to order and opened by the reading of an address by the chairman.

Stone in the Kidney and its Operative Treatment was the title of the address delivered by Dr. Joseph Ransohoff, of Cincinnati. Stone in the kidney is not a rare affection. Many cases are found only at autopsies, no tangible symptoms existing during life.

On the other hand, no other affection of the kidney is so often erroneously supposed to be present as stone.

Crystals in the urine do not absolutely indicate stone in the kidney. Many cases have been operated on for stone where crystals persisted, but stone was found. On the other hand, stone has been found where no crystals existed.

Red-blood Disks.—These are far more important when existing at every microscopical examination made, and especially so when associated with acid pyuria. This is especially valuable when by the aid of the cystoscope we eliminated the bladder.

Operative Treatment.—Choice must be made between simple incision and extirpation or partial resection of the kidney. As to the latter operation it should only be used as a last resort. Large size, confirmation, and multiplicity of the calculus ought not to weigh in favor of nephrectomy, since with longitudinal incision along the renal convexity, ample room for manipulation can be obtained.

Where shall Incision be made?—Hemorrhage and the end result as to a cure without a renal fistula must be our guide. Along the convexity of the gland, therefore, the longitudinal section made as in an autopsy would be the least likely to wound the larger vessels, and the resulting hemorrhage would be parenchymatous, which could be reduced greatly by temporary compression.

Fixation of the kidney should be the concluding act of every operation upon the kidney.

Summary.—In conclusion, the following theses are presented for consideration :

1. An absolute diagnosis of stone cannot be made.
2. Nephro-lithotomies must be divided into those of necessity and of choice.
3. Pyuria and microscopical hæmaturia, as evidences of beginning destructive changes, are positive indications for operative exploration.
4. The oblique incision is to be preferred for the ease with which it permits the exploration of the entire kidney.
5. Acupuncture is not to be relied upon.
6. Incisions should be made along the convex border, and only when the circulation is controlled by digital compression.
7. Incisions into the pelvis of the kidney for exploration and removal of a stone are to be avoided.
8. Primary nephrectomy for stone should be reserved for extreme cases.
9. Primary union by suture, where feasible, makes nephro-lithotomy an ideal operation.
10. Tight packing of the kidney wound and prerenal space endangers the nerve-supply of the colon.
11. Nephrorrhaphy should form the closing act of every operation which has seriously disturbed the relations of the kidney.

Æro-urethroscopy was the title of a paper read by William K. Otis, M.D., of New York City. Since the invention of the original illuminating apparatus little, if any, change has been made in urethroscopic tubes. In 1892 the first instrument combining air inflation and illumination was made by E. Hurry Fenwick, of London. This instrument was cumbersome and heavy, and the distance between the glass of the diaphragm and the meatus is over two and a quarter inches. In making application the diaphragm must be removed, laid aside, and replaced, making an annoying break in the rhythm of the operation. The illumination from the concave mirror is inferior to that of a plano-convex lens. All these objections the author of the paper claims he has removed in his perfected instrument, in which the diaphragm is placed on a pivot and can be swung aside when making applications.

The advantages claimed for this instrument are :

1. Ready access to the urethral field for the purpose of making local applications under the direct control of the light.
2. Minimum distance between the eye and the urethral mucous membrane, hence a better and clearer view of the field.
3. Extreme lightness.
4. Simplicity of construction and moderate cost.

The difficulty in obtaining a thorough appreciation of the morbid conditions present in many obscure cases which present, when the urethra is implicated, despite its many drawbacks the aero-urethroscope furnishes us with a new means for investigation and an aid to diagnosis which no urethroscopist of the present day can afford to ignore.

Value of Urethroscopy in Chronic Urethritis was the title of a paper read by Dr. Ferdinand C. Valentine, of New York City. This paper was practically a demonstration of instruments, divided into four parts :

Modern Urethroscopy.—The instruments shown were the Posner urethroscope, which is practically a prolongation of the old meatoscope without an obturator. It is made in two forms, a tube vertically cut off ; the other terminating obliquely, illuminated by light thrown in at the top of the funnel.

The Casper Urethroscope is a more extensive apparatus. The tubes are longer than the Posner. They have an obturator and at the visual end a rim fitting into a handle provided with condensers and prism by which electric light is reflected into the urethra. This instrument requires considerable experience in its use to be valuable.

Nitze-Oberlaender Urethroscope.—This has a light-carrier which is inserted into the tube, placing the light at the points examined, the urethra being protected from the naked light ; two small tubes allow a current of cold water to flow around the light.

Cystoscopy.—In renal diseases the cystoscope is of surpassing importance. The patient passing blood or pus, by the use of this instrument we can eliminate the bladder and tell which kidney is affected.

Catheterization of the Ureters.—This, as is well known, is done with the aid of the cystoscope, and after inserting the catheter in place the cystoscope may be withdrawn, enabling us to see the urine ejected in spurts of a few drops at a time at regular intervals, and giving us urine free from vesicle contamination, whereby we can make an absolutely correct microscopical examination.

SECTION ON DISEASES OF CHILDREN.

First Day, Tuesday, May 7th.

Address by the Chairman.—Dr. Edward H. Small, of Pittsburgh, Pa., remarked that this was the sixteenth meeting of the Section. The address was devoted entirely to business matters.

Typhoid Fever in Infancy and Childhood.—Dr. William B. Noyes, of New York, read the paper. Although the subject had been much discussed in late years the author ventured to bring it up again on account of the great uncertainty prevalent regarding it. While some authors spoke of having seen many cases of the disease, others, such as Northrup and O'Dwyer, of the New York Foundling Asylum, were sceptical of its occurring in childhood. This asylum has seen nothing of it. The Nursery and Child's Hospital does not record it. The Children's Hospital of Philadelphia reports never to have seen a case, where there is the largest children's service in the United States.

In contradistinction, however, there are many observations of it in European institutions. In London, 1870–1871, one hundred and twenty-six deaths occurred under five years of age, eighteen per cent. of all cases. In 1880, 58 deaths, thirteen per cent. In 1881, 83 deaths, eight per cent. of all deaths from the disease.

French institutions also give reports of the disease, as do those of Berlin and other European cities.

It is not so important to know whether the disease among children ever occurs sporadically or only during

epidemics, as it is to be able to diagnose it in particular cases when actually met. It is particularly liable to be mistaken for something else, such as malaria, gastro-enteritis, broncho-pneumonia, tuberculosis, or meningitis. Pathological lesions—the ordinary lesions of typhoid. In infancy all the abdominal viscera will be found congested. The swelling in Peyer's patches occurs earlier in children than in adults. On the whole, however, the changes are less severe. Sanarelli's experiments on animals show that the artificially produced disease shows almost the identical condition as that described as found in children.

Diagnostic Symptoms (as characterizing the disease in children particularly).—Long continued fever, not yielding to quinine, of gradual onset, highest in the evening when there are conditions existing in the throat, lungs, bowels to offer explanation. The continuous fever seems to be well borne, the child plays about with little prostration often.

Gastro-intestinal disorders and constipation, or putrid stools if diarrhœa be present. The diaper is apt to absorb the fluid which gives character, pea-soup, to the diarrhœa, which will be observed if discharged into a vessel. Lack of acute symptoms of an intestinal nature. Tongue symptoms similar to those in adults, but sordes and extreme condition not so apt to occur.

Symptoms.—Fever, lenticular spots; these may occur early or late, in two or three crops. Headache, indicated by rubbing or picking at the head, nose, or ears, burrowing the head into the pillows, but not by active symptoms like those of meningitis. Important to make out enlargement of spleen, but not easy in the young—a painful spleen more important point. Tympanites present, usually moderate. Bronchitis would seem to be a regular symptom. The bronchia excrete the Eberth bacilli, it has been demonstrated. Angina has been observed. Epistaxis is rare.

Neither in children nor in adults can the Eberth bacillus be demonstrated in the stools until the tenth to the twentieth day. It is doubtful whether it has been demonstrated reliably in children. A number of authorities have failed to do it in adults. The stools swarm with all sorts of bacteria. The disease appears in three forms—an abortive type of short duration; a type resembling the ordinary one of adults; a malignant or prolonged type. Convalescence, as a rule, is quicker than in adults, and the mortality is less. Abortive cases are frequent, according to a number of observers. Many cases last from eleven to twenty-one days in children. Still these cases may have all the characteristic symptoms of the protracted disease. It should be borne in mind that other acute conditions produce changes in Peyer's patches and in other parts of the intestine in children similar to those of typhoid.

After the ulceration has occurred the condition in typhoid is one of septicæmia. As the disease progresses the specific bacilli become less numerous, while other kinds multiply, such as the streptococcus, pyogenes aureus, albus, etc. Possibly the abortive cases are those in which the bacillus of Eberth alone operates, while severe cases are those in mixed infection, analogous to conditions present in other diseases, such as diphtheria, scarlet-fever, etc.

Dr. John E. Woodbridge, of Youngstown, O., then read a paper on the same subject. It is the same disease, and governed by the same causes, at whatever age it occurs. The morbific agent is present. It only varies by the amount and quality of this and the degree of intoxication. Every case of typhoid fever may be aborted by proper treatment, and by a mild method, too, of treatment. Treated symptomatically, it is very grave and fatal. The general practitioner does not adequately realize the actual frequency of this disease in children. Text-books hardly mention it. Still, my experience shows it not infrequent. Three-fourths of cases of so-called brain fever are typhoid fever; so of congestive fever and meningitis, they have been in many cases proved on autopsy to have been typhoid fever. Cases were referred to by the author of several reporters of eminence. It is very important that this prevalent opinion regarding the absence or rarity of typhoid in young children should be corrected, to avoid the fatal results of erroneous treatment most particularly. Intestinal hemorrhage rare in author's experience in children. The author illustrated the points of the paper by a number of cases.

The danger of mistaking the disease was illustrated in relation to treatment.

Treatment.—Disinfection of the intestinal canal by carthartics and antiseptic medicines. Diarrhœa is not a contraindication for flushing out the intestines by catharsis; medicines should by copious draughts of fluids.

Malaria in Children.—Dr. W. S. Thayer, of Baltimore, read a paper on this subject.

Paper discussed the disease in relation to the malarial parasites. Three varieties named: Intermittent, remittent, so-called typhoid malarial.

In intermittent the parasites are present in enormous numbers in the blood. The paroxysm is supposed to be due to some poison suddenly set free by these parasites in some way unknown at present upon their accumulations at periods in the blood. The various period of paroxysms are due to different characters of the parasite in the system. The regular types occur more early in the season, while the irregular ones later in the autumn. The discovery of these parasites is the only means of positive diagnosis.

The parasites are the same in children as in adults. The demonstration of the plasmodiæ is not difficult. Take a clean cover, slide, and glass. Take the blood from the finger—in children better from the lobe of the ear, while asleep or so as not to be seen. Touch the drop of blood with the tip of the cover-glass in taking it up so that the blood will spread better—small drop—cover and spread and dry in the air; stain and mount; stain in aqueous solution methylene blue.

Guaiacol in Typhoid Fever.—Dr. Adolph Koenig, of Pittsburgh, Pa., read a paper on "Guaiacol in the Treatment of Typhoid Fever in Children."

The increase in frequency as age increases of typhoid fever is probably due to greater exposure of the intestinal canal by diet and drink. When the ulcers of the intestines have occurred, the treatment of the disease resolves itself into that of surgical antiseptics and disinfection.

Initiatory Treatment.—Clear out the bowels by calomel, triturated with sugar of milk, $\frac{1}{10}$ grain every hour.

Regular Treatment.—A mixture of guaiacol is given throughout, and other measures as may be indicated. Cold sponging alone is used as an antipyretic. No depressing medicines for this purpose should be used. Guaiacol is not regarded as a specific, but as a feasible antiseptic remedy.

Brandt Method in Children.—Dr. Samuel S. Adams, of Baltimore, read a paper on this subject. In the summer of 1893 the method was put in use at the Children's Hospital. The charts of the hospital since that date speak more strongly in favor of the treatment than anything else. The only real test of the method is to apply it in all details as directed by its author, and the application should be directly under the supervision of a competent physician and not entrusted to a nurse. The bath must be taken to the child, not the child to the bath—bathe at the bed side. A teaspoonful of whiskey before giving the bath. Begin with water from 70° F. to 80° F. Next day it may be of lower temperature, if well borne with this temperature the bath will reduce the child's temperature very considerably. Always take the temperature in the rectum in children. It is not reliable taken in mouth or axilla. Delirium will be removed after a bath; sleep often being produced immediately. The delirium, if it recurs, will always be of milder character. Tempera-

ture charts of cases were displayed by the reader of the paper to illustrate the effects of the method as employed in his own hospital cases.

The only death in the service since August under diligent tub-bathing was one in which there was a false diagnosis. The author also related a case in which there were periodical hemorrhages, delirium, and other serious complications, the case lasting seventy-two days, in which there was at times high temperature, requiring over seventy baths. The case recovered, notwithstanding all expectations to the contrary.

Dr. William Osler, of Baltimore, agreed that the course of typhoid is, on the whole, milder in children than in adults. He had noticed the tendency to its onset with head symptoms. It was not an original observation, for Dr. Enoch Paine, of Boston, many years ago, had noticed the lesions of Peyer's patches in other diseases than typhoid fever in children. Autopsies more recently have corroborated this.

Treatment is the burning question after all. Whether it is not better not to say anything than to come forward with such positive statements as made by Dr. Woodbridge, is a question. It is not in accordance with truly scientific practice to make wholesale claims. It is more like newspaper work than science. The remark referred to was the claim that there was no excuse longer for the loss of a single case of typhoid fever seen at an early period and in which a diagnosis was made. The speaker preferred the trained nurse to the house physician to administer Brandt baths.

Dr. William Pepper spoke of the difficulty of diagnosis, especially in presence of the many germ diseases, known and unknown, which confuse the situation.

He has been treating typhoid in children over thirty years—feels more and more modest as his experience increases. The ultimate test in diagnosis will rest upon correct bacteriological and chemico-physiological conclusions.

The Brandt treatment is capable of misapplication and misuse, should not be adopted with unvarying routine, but by intelligent individuation of cases, like all other measures or methods. But in ordinary cases it is of great benefit.

Disinfection of the Intestine, and Antisepsis.—The use of some remedy which shall prevent or modify the toxication of the system, if it may be found, is the great desideratum. The direct local treatment by diet and disinfection before the necessity of the application of Brandt's treatment will save cases, lost otherwise, whatever may be done after the poison has been absorbed beyond a certain degree. Liberality should be practised in treating this disease. Dogmatism should be avoided.

Dr. J. A. Work, of Elkhart, Ind., continued the discussion, among other things remarking that elimination of the poison is the first measure in the treatment, then apply antisepsis.

Dr. George N. Acker, of Washington, remarked that he and Dr. Adams were on the service of the same hospital, but he depends more on other means than Brandt's method. He has discontinued its use, largely because of its depressing effects. Prefers to use water by means of spinal compresses and other less vigorous means than that of Brandt.

Dr. Atkinson, of Baltimore, remarked: The error of diagnosis in typhoid fever in children is largely due to the general expectation that the disease runs a typical course. As soon as we cease to look in children for the typical case of typhoid and acquaint ourselves with the actual conditions which do occur in the course of the disease, then it will come to be recognized.

As regards the Brandt bathing, the good results are not by any means confined to the single one, that of reduction of temperature. Its merits are apparent as well in the general improvement, the checking of delirium, the quieting of nervous symptoms, restlessness, the inducing sleep, etc. Of course this method should not exclude rational measures of other kinds. Removal of toxic intestinal accumulation and antisepsis especially, must not be neglected in the present state of our knowledge of the nature of the disease.

One speaker emphasized the importance of judicious stimulation, which thus far no one had referred to. Another speaker referred to the impracticability of relying upon bacteriological examinations for diagnosis in this disease, because, as was shown by the reader of one of the papers, Eberth's bacillus was not discoverable until from the tenth to the twentieth day in the intestinal discharges.

Dr. Larraby, of Louisville, Ky., remarked in part: We boast about wonderful advances in medicine, but the doctor of fifty years ago would not be at much disadvantage in the present discussion. We do not seem to have got at much that is reliable beyond what he knew. He spoke of the characteristic hebetude, the typhoid headache, etc., which he thought must be present to render diagnosis reliable in children, as well as in adults. But in the progress of the disease in children the third week was wont to be cut off.

Is the chief object of treatment to keep the patient comfortable? or is it not to abort and modify the actual disease? Is it important to suppress the temperature, for that is what lowering by baths really does. As for how to actually abort or to modify the disease, the speaker ventures to express the opinion that we are not far from where our fathers were.

Another speaker remarked that we have no specific yet, we must therefore rely upon rational methods which experience has taught to be useful—bathing being one of the most useful of these.

Dr. S. Solis Cohen was very emphatic in pointing out the errors of those who spoke of the Brandt treatment as one whose object was to lower the temperature. It does two things more particularly. First, it alleviates nervous irritability, calms excitement, and allays delirium. Second, it stimulates metabolism. It has been shown that urotoxic elimination is increased by cold bathing, etc. These are the real objects of cold bathing, the lowering of temperature is incidental, important though it may be.

It is absolutely important that the patient should be put in a warm bed and stimulated after the Brandt bath in order to prevent depression.

Dr. Woodbridge, in rebuttal of criticism, asked if the speaker would pronounce him derelict for not employing Brandt baths, etc., when without these he had for eighteen years treated thousands of cases without any death. He believed that within five years, notwithstanding present severe criticisms, a method of treatment, he would not say his own, but one on the lines of it, would be adopted which would result in the absolute elimination of the mortality of typhoid fever.

Dr. Adams in rebuttal remarked that he believed that he had been misunderstood in his reference to the supervision of baths by the house physician. He expected the nurse to apply the bath, but under skilled supervision. He further remarked that he was not aware of any reliable means of intestinal disinfection for the disease.

Revolt of Italian Students.—The University of Naples was recently closed for a year on account of insubordination of the students. Soon after this a meeting of Roman students was called together in the college quadrangle to express sympathy with their fellow-students at Naples. This was so disorderly that the police were called. The students then held a mass meeting in the Colosseum, which ended in a fight with the carabineri. The faculty being unable to enforce discipline, Dr. Baccelli, the Minister of Public Instruction, closed the University of Rome for a year, as he had before that at Naples. The other universities are now in trouble, and even the advanced school for higher studies at Florence is affected.

MEDICAL AND CHIRURGICAL FACULTY OF THE STATE OF MARYLAND.

Ninety-seventh Annual Session, held at the Hall of the Faculty, Baltimore, April 23 to 26, 1895.

DR. ROBERT W. JOHNSON, PRESIDENT; DRS. JOSEPH T. SMITH AND ROBERT T. WILSON, SECRETARIES.

FIRST DAY, TUESDAY, APRIL 23D.

THE ninety-seventh annual session of the Medical and Chirurgical Faculty of the State of Maryland was called to order at twelve, noon.

Pernicious Delay in Surgical Cases.—This was the subject of the address by the President, DR. ROBERT W. JOHNSON. (See page 578.)

Certain Sanitary Needs of our City and its Public Schools.—This was the subject of a paper by DR. EDWARD M. SCHAEFFER, in which he spoke first of the large number of cows and cow-stables within the city limits, their unsanitary condition, and the fact that these cows were never taken from their stalls except to be milked. He showed what good the Milk Inspection Act had wrought. Then he dwelt on the importance of cleanliness, and especially personal cleanliness and the needs of increased facilities for public baths. The defects in the public-school buildings were manifold, in lighting, in ventilation, often in heating. The hygiene of all that pertained to schools and scholars was considered and suggestions were made.

A Plea for the Sight of our Little Folks.—This was the title of a paper by DR. GEORGE A. FLEMING. Few persons are born blind. The majority of causes of blindness and defective eyesight are preventable. The eyes of infants are sensitive. Exposure to great light, negligence in cleansing the eyes of the new-born, accommodation defects from the too early use of the eye, as in kindergartens, and other causes, are responsible for eye defects and blindness.

DR. E. M. SCHAEFFER was glad to hear of papers of such educational value, and thought the subject of child life one that was less understood than any other department of medicine. Professor Stanley Hall had pointed out the fact that much too minute work is expected of children's muscles. Delicate work for the eyes should be discouraged.

Typhoid Fever in Country Districts.—This was the subject for general discussion before the Society. DR. WILLIAM OSLER said: The dwellers in cities have a very deep concern in the prevalence of typhoid fever in country towns and districts. In the first place we treat in the city many cases that originate in the country, cases which too often go to swell our mortality bills. During the past six years I have had under my care in the public or private wards of the Johns Hopkins Hospital 89 cases which came from outside the city limits. The figures are as follows, from a total of nearly 400 cases: From Baltimore County, 58; from Maryland, outside Baltimore County, 14; from outside Maryland, 17.

Secondly, we take our holidays in the country at the latter half of the summer and in the autumn, the very seasons when typhoid fever is most prevalent. Since we have no means of knowing the number of cases which occur annually in the city, we have, of course, no way of ascertaining how many have been the unfortunates who, in seeking health in country resorts and seaside places, have found serious illness, and not infrequently, death. General impressions are not of much value, but I think there are many doctors in practice in this town who could give some specific figures as to the number of persons who have returned to town with the disease, or who have been attacked while in the country. Cases of the kind have not infrequently come under my observation during the past five or six years, and I know of instances in which many members of a family have been infected during their residence in country places.

Thirdly, our water supply is derived from streams which pass through fairly populous districts in which every autumn typhoid fever prevails.

And lastly, the country sends daily for our consumption an enormous quantity of food material, namely, milk, which is especially liable, under suitable circumstances, to infection with typhoid germs.

The following questions may be profitably discussed by this meeting: First, the prevalence of typhoid fever in country districts. We naturally turn for the statistics to the Report of the State Board of Health. So far as I can read in the last published report of this body for the years 1892–93 the references to typhoid fever are very scanty, and no statements are to be found from which one may glean any information about the incidence of the disease in the counties and towns of the State. I would like very much to ask the Chairman and the Secretary of the Board the reasons for this omission. The matter is of extreme importance and directly concerns the health of the city. There were 257 deaths (I include the typho-malarial fever) last year (1894), but who can tell us how many cases? Shall we put the mortality at ten per cent. and say 2,570, or at fifteen per cent., and say 3,855 cases? We may take no small shame upon ourselves as a profession that such a state exists. It is useless to scold Dr. McShane, or to abuse the members of the State Board of Health. Such a condition at this end of the century is a disgrace to us as a profession, and to us individually. The Report of the State Board, to which I referred, indicates weakness, inherited or acquired, of a most disastrous quality, and if any member of this ancient and honorable Faculty can read the same without a blush I am sorry for his intellectual medulla. The notification of every case of typhoid fever in the city and throughout the State should be enforced at the earliest possible date. We could then ascertain the percentage of cases which really originate within the city limits, and by a proper system of co-operation of the County and State Boards every local outbreak could be studied and precautionary measures taken.

A second question, which can be discussed with advantage, relates to conditions in the smaller towns and country places favoring the development and spread of typhoid fever. Outbreaks of typhoid fever in a town like Cumberland, in which the people had been drinking water contaminated by the sewage of from one-fifth to one-fourth of the population, are of course not remarkable. But such outbreaks are not nearly so dangerous to us in the city as the smaller house-epidemics in country places, which are by no means uncommon. In many of these it is extremely difficult to trace the infection. There are instances, as the remarkable one I put on record a few years ago of a farm-house in Hartford County, in which, during the months of August, September, October, and November, there were ten cases with four deaths; nine of these followed the arrival of a member of the family from Ocean City with what was thought to be malaria, but which turned out to be severe typhoid. The water supply in this instance was certainly not contaminated, since it was used in common with another large family consisting of many persons at the susceptible age. Here the food supply might have become in some way infected, though Dr. Sappington, who had charge of the cases, seemed to think that it was most probably transmitted by direct contagion.

A State Board of Health of any efficiency would receive early notification of every house outbreak, and with a proper corps of inspectors suitable means could be taken to prevent, at any rate, diffusion of the poison. How interesting it would be to know just how many cases of the disease occurred last autumn along the watershed of the Gunpowder and Jones's Falls, both of which streams are liable to pollution. We can never be free from danger on this score until the city has complete control of the streams.

The third point for discussion, and in reality the most important one, relates to the possible contamination of the milk-supply of this city. How many cases of typhoid fever occur in the families of those who in this State supply milk to the citizens of this town? Can Dr. McShane answer, or can any member of the State Board of Health answer? Or if they cannot, can they tell us how to obtain the facts of our next typhoid season so that an answer could be given? The dairy industry, as we all know, is enormous, and one of the greatest import in the health of the city. The readiness with which typhoid fever is transmitted by milk has been amply demonstrated; nor does it require that a man ill himself with typhoid fever should milk cows or be in contact with the milk. A man whose boy is ill with the disease, or the woman who has been nursing her daughter, may readily, in several ways, carry the infection. As a medium for the development of the typhoid bacilli milk is well known to be most favorable. It is not alone from the water of a contaminated well used for washing the milk-cans that infection arises, but in many instances from the direct contact of the dirty hands with the milk, or the vessels in which it is placed. The only possible safeguard is in a rigid system of inspection of every dairy which supplies milk to the city, an inspection which should be frequent, systematic, and thorough.

I have no desire to take up the time of the faculty with figures from other localities. There are those which show, as in New York State, that while typhoid is progressively decreasing in our large cities, it is progressively increasing in the country districts. Baltimore, with a mortality from this preventable disease of between 5 and 6 per 10,000 of population, ranks with the unsewered towns, the sanitary conditions of which are still antique. We shall probably never reduce the death-rate from this disease to the ratio of modern cities until the cesspool system is completely abolished. But before that great work is undertaken the citizens should demand that at any rate the sources of contamination from outside should be reduced to a minimum; that our sources of water-supply should be scrupulously guarded; and that our citizens should be guarded against all possibility of infection through the milk.

The points, I think, which could be discussed with advantage this evening are: first, the actual prevalence of typhoid in the country districts and small towns throughout the State; second, the measures which should be adopted to prevent contamination of our water-supply; and thirdly, the question of the inspection of dairy farms.

Dr. Charles M. Ellis, of Elkton, thought that country typhoid was much less fatal than its city congener. Vital statistics in country districts are usually received with distrust. In 1884 and 1885 there was a typhoid epidemic in Elkton from infected milk. In the twelve months following there were one hundred and thirty cases with three deaths. English statistics give higher rates. The advantages of country salubrity are offset by the good nursing of the city. Of the cases of milk origin, none were fatal, which made him think that perhaps milk cases were less fatal than water cases. It is very hard for a physician practising in a malarial region not to believe in such a disease as typho-malaria. In spite of systematic writers to the contrary, the two diseases are so often combined as to very effectually influence each other. Many towns have a good water-supply but have no sewerage system. It is not the throwing out of the typhoid dejecta in the privy vaults that does the harm and spreads the disease, but throwing it out on the surface under the impression that this is a safer method. From here it finds its way into neighboring wells. Those who use well water run greater risk than those using water from a water supply. There are many difficulties of enforcing sanitary laws in small towns and in country districts. The township system would be a great benefit to Maryland. Scrupulous cleanliness in the sick-room, the instant disinfection of each stool as it is passed, the care of the bed-clothes and the proper choice of food are what can be done anywhere.

Dr. C. Birnie could only speak for his part of the State. They had had one general epidemic of that disease and several local ones. The mortality was about five per cent. The water-supply may be at fault, but the question is an exceedingly complex one. Typhoid fever depends also on the channels of the water-supply, the flow of the ground-water, the trend of the rocks. Other factors than the mere presence of the germ cause the disease. He has seen a sudden outbreak from a sudden thaw after a hard freeze flushing all streams and wells. Similar conditions may be existing for years when suddenly in some unexplained way an outbreak will occur. He thought that bored wells were the safest. The general impression is that springs are better, but they are liable to receive the surface drainage, and as they are generally at a low level, may receive the overflow from the privy pit. Strict sanitary laws are needed in the country. As it is the health officer in country districts has very little authority, and has a thankless task; and unless he has much tact he is constantly offending other physicians and their patients.

Dr. James F. McShane, Health Commissioner for Baltimore, spoke of the water-supply of cities and small towns and the methods of preventing infection. He had little knowledge, he said, of country water-supply, but he spoke against the open well as drawing to itself impurities in the soil for long distances around.

Dr. L. E. Atkinson, in referring to Dr. Osler's remarks, thought there was a great difference between statistics in and out of a hospital. Some cases were so atypical that they did not come under the physician's care at all. These cases of ambulatory typhoid are often not recognized until in some cases sudden death reveals the eroded intestine. This makes the mortality much smaller when such cases are taken into consideration. Want of cleanliness or care on the part of a young and inexperienced nurse may spread the disease. It is caused by the water-supply and by milk, and the latter is more often the cause than is generally supposed.

Dr. George H. Rohe thought that many cases of acute tuberculosis were mistaken for typhoid fever. Many cases spread the disease through ignorant and inefficient attempts at disinfection, because so many persons thought that the addition of one of the many so-called disinfectants killed the germ. Too many of the so-called germicides are entirely inert. Water at 130° F. will destroy the typhoid germ. Let the water boil and by the time it is added to the stools it will still be hot enough to disinfect.

Dr. William H. Welch said it was difficult to trace the origin of the disease, especially in a given case or a group of cases. We are inclined to be too adherent to one exclusive source, such as water, milk, etc. It may come from the soil, from the dust. We have no proof of this, but it cannot be disproved. Even the spontaneous origin cannot be disproved, but it cannot be proved. Rubner says the typhoid bacillus may be a saprophyte. All agree that the special point is in the prophylaxis. Good water, clean milk, are necessary, and we should do everything possible to improve the sanitary arrangements in all directions. Special problems relate to typhoid fever in country districts. One is the great reluctance to recognize the disease, perhaps due to local patriotism. It is an index of the sanitary condition of that district. It is considered a reproach to have the disease in large amount. We should have information of the number of cases in any district, not for curiosity but for sanitary reasons. He heartily seconded the suggestion of Dr. Osler to stir up physicians to unite and learn all they can about this disease. The city should be protected beyond its boundary. There should be

co-operation between city, State, and county boards of health. One reason why we are so backward is because we have no national board of health. Disease does not respect artificial boundaries. The national need not interfere with the State board but only as a co-ordinating agent. He agrees with Dr. Atkinson that we must have central filtration; self-purification is a delusion and a snare. The detection of the typhoid bacillus in water is very difficult; so difficult that it has no practical value. The typhoid bacillus lives from six to eight to twenty days in water, and in the soil for an indefinite period, at least three months. The incubation period of the disease is twenty to twenty-two days. We should guard against contaminating the soil, and must not be too hasty in blaming the milk or water. The detection and demonstration of the bacillus in these liquids is very difficult. No house can stand a too minute examination; some sanitary defect will be found, and the physician is satisfied, when, perhaps, he has not discovered the real cause. A thorough cleaning up on all sides reduces the chances of the disease.

Dr. James A. Steuart, Secretary of the State Board of Health, said that absence of vital statistics throughout the State was due in part to the apathy of the physicians of the State.

The question was further discussed by Drs. Thomas S. Latimer, John R. Uhler, and William Osler.

"Subconjunctival Injections in Profound Ocular Inflammations," was the subject of a paper by Dr. E. J. Nernstein. "Surgery of the Nasal Septum," was a paper by Dr. George Thomas.

Second Day, Wednesday, April 24th.

"The Quantitative Determination of the Rennet Zymogen; its Diagnostic Value in Certain Diseases of the Stomach," was the subject of a paper by Dr. Julius Friedenwald. "Case of Syphilitic Endocarditis Causing Mitral Insufficiency." This was by Dr. Charles O'Donovan.

Peritonitis Caused by Invasion of the Micrococcus Lanceolatus From the Intestine.—Dr. Simon Flexner read this paper, in which he said that several cases had been reported of acute purulent peritonitis in which this organism had been found as the cause. It escapes from the intestine into the peritoneum, and he wished to report two additional cases. He described the micrococcus lanceolatus. It does not possess great vitality. It is strange that it can reach the intestinal canal. The easiest mode of ingress is by being swallowed, were it not that the stomach secretions quickly destroy it. It passes the portal of the stomach at a time when the secretion is not acid. Once there it is capable of being developed, but not to a great degree. It causes dysentery. It is not present in great numbers. It passes through the intestine at a place where it is weak. In one of his cases there was a chronic dysentery with acute exaccerbations and in another case there was pelvic peritonitis, with which he had been ill one week before coming into hospital.

This paper was discussed by Dr. P. C. Williams.

Dr. John W. Chambers read a paper on "Note on Sarcoma with Reports of Cases."

Bullet Wounds of the Liver and Stomach—Closure by Tampons.—This was a report of several cases by Dr. L. McLane Tiffany. It was a bullet wound of the upper abdomen, where operation is so difficult. By suture and tampon he saved the patient. Immediate operation was the important point.

The paper was discussed by Drs. R. Winslow and R. W. Johnson.

"Aseptic Cultivation of Protozoa," by Dr. C. O. Miller, and "Protozoic Infections with Demonstrations of Photomicrographs and Specimens," by Dr. T. C. Gilchrist was a very elaborate paper.

The Relation Existing Between Gall-stones and Hepatic Abscess.—This was a paper by Dr. W. M. Lewis, in which he showed how great care in examining the blood and urine helped him toward the right diagnosis.

Dr. William H. Welch said that the bile duct was free from bacteria, except at the mouth of the common bile duct. Bile has very slight antiseptic power, and we cannot explain the absence of bacteria. It is very common for bacteria to wander from the duodenum into the bile duct. A very large number of bacteria perish in passing down the intestine, but in the duodenum they have not as yet perished, and we have a greater number of them and a greater variety. If gall-stones are present, the opportunities are favorable for a growth of the bacteria. The formation of abscesses circumscribed is very rare. The bacillus coli communis is very common in the gall-stones. There is no evidence that the bacillus coli communis can cause abscesses. He has been much interested in the bacteriological formation of gall-stones. There is a relation between the presence of the bacillus coli communis and gall-stones. He had been making cultures from the interior of gall-stones, and in the great majority of cases he has found a pure culture of the bacillus coli communis in the interior of the gall-stone with no bacilli on the outside. The microscopic examination of the pus from liver abscess helps sometimes. It looks like pus with the naked eye, but it is not; it is only broken-down tissue, detritus, etc. This is peculiar to the abscess of the liver due to the amœba, and other kinds do not cause this.

Third Day, Thursday, April 25th.

"Experiments on the Motor Functions of the Stomach," "The Effect of Digestive Diseases on the Heart." These were two papers by Dr. John C. Hemmeter.

The Relation of the Different Types of Malaria to the Seasons of the Year.—This was the subject of a paper by Dr. William S. Thayer in which he said in the various forms of malarial fever the parasite enters into the blood-corpuscle and destroys it, and we have the disease. The parasite develops and undergoes sporulation and at this time a paroxysm takes place, and on the time of sporulation depends whether it is tertian, quartan, or quotidian. In his statistics cases were recorded in the dispensary in every month, but more in July, August, and September than in the other months. In four hundred and fifty-two cases collected, one hundred and thirty-one occurred in the first half of the year, and three hundred and twenty-one in the second half. Most of these were tertian.

Dr. J. C. Harris thought it was important to know where these cases came from.

Dr. I. E. Atkinson said that in his experience in treating cases of winter attacks of the disease he found that if the patient has not had previous attacks, he had been in the locality where he might have had them. He believes from clinical experience that malaria does not originate *de novo* in the months when the temperature runs to freezing point. Those cases carry the organisms in the body, and it does not develop until the vitality is lowered.

Dr. James A. Steuart referred to drinking water as a cause. The paper was further discussed by Drs. G. J. Preston, J. E. Michael, C. O. Miller and S. A. Keane.

"The Treatment of Puerperal Fever—a Warning Against the Indiscriminate Use of Corrosive Sublimate." This was a paper by Dr. J. Whitridge Williams, which was discussed by Drs. J. H. Branham, B. B. Browne, A. K. Bond, Wilmer Brinton, and J. E. Michael.

The following papers were afterward read and discussed: "Persistent Uterine Hemorrhage; its Source, Dangers, and Treatment," was a paper by Dr. Thomas A. Ashby, and was discussed by Drs. R. M. Hall, G. H. Rohe, and J. R. Uhler.

"Careless and Unscientific Midwifery, with Special Reference to Some Features of the Work of Midwives," by Dr. W. S. Smith; "Pelvic Disease and Insanity," by Dr. George H. Rohe; "Tetany, with Report of a Case," by Dr. George J. Preston; "Tetany During Pregnancy," by Dr. H. M. Thomas; "Heredity as a Factor in the Etiology of Idiocy," by Dr. S. J. Fort.

The Causation of Nervous Diseases.—This was the subject of a masterly effort by Dr. M. Allen Starr, of New York, being the Annual Oration before the Society. The knowledge of the cause of disease is most important for a correct understanding of that disease and its proper treatment. After going into the minute anatomy of the nerves and their physiology, he spoke first of exhaustion from overwork and then of defective nutrition from imperfect blood-supply. He concluded the whole with hints at treatment. The address was greeted with applause, and requested for publication in the annual Transactions of the Society. Dr. Starr was then elected an honorary member of the Society.

Fourth Day—Friday, April 26th.

"Melæna Neonatorum" was the subject of a paper by Dr. W. M. Lewis.

Recent Improved Methods of Infant Feeding, with Especial Reference to Modified Milk.—This was the subject of a very practical and instructive paper by Dr. Robert Tunstall Taylor, who compared human milk with cow's milk and showed the importance of getting as perfect a substitute of mother's milk as possible when the latter was not obtainable. He spoke against all baby foods on general principles, and paid a tribute to the Walker-Gordon laboratory for the furnishing of pure milk to families for infants, and as a result of this paper it was moved to appoint a committee to take steps toward the getting a milk laboratory in Baltimore.

The following papers were then read: "The Significance of Variations in the Calibre of Retinal Arteries," by Dr. Harry Friedenwald; "A Contribution to the Study of Pseudo-Membranous Conjunctivitis," by Dr. Hiram Woods; "Three Cases of Purulent Membranous Otitis Media, which ended Fatally," by Dr. William F. Lockwood.

Election of Officers.—The following officers were then elected for 1895–96: *President*, Dr. J. Edwin Michael; *Secretaries*, Drs. John S. Fulton and Robert T. Wilson; *Treasurer*, Dr. W. F. A. Kemp.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, April 5, 1895.

Henry F. Walker, M.D., President, in the Chair.

Salivation of Seven Months' Duration.—Dr. W. Gilman Thompson presented a man who had suffered from salivation and its results for seven months—a Scotchman, about fifty-four years of age, married thirty years, no syphilitic or neurotic history, not addicted to alcohol, in ordinary good health until about seven months ago. At that time he noticed that his gums, anteriorly, on the upper jaw, became quite black, as he described it, and he applied to some physician who told him that it did not amount to much, and gave him a mouth wash. Shortly after that the whole gum became swollen and hard, lower as well as upper, and almost at the same time he began to salivate a good deal. The flow of saliva was so excessive that at night he had to collect it in a towel. About this time also his lips became very much swollen and considerably eroded. The tongue and speech had not been affected. What had continued to annoy him most was the swelling and intense burning sensation in the lips. All sorts of applications had been made by the different physicians whom he had consulted, without much benefit. The lips became excoriated, and the patient had an idea that the saliva was acid and on that account caused the swelling and erosion of the lips. By test it was faintly acid.

Although there was no history of syphilis, Dr. Thompson had tried iodide of potassium, and had succeeded in carrying it up to fifty grains a day, with the result of producing greater relief than by any other measure, but he had been compelled to diminish the amount on account of diarrhœa. Since reducing the iodide the improvement had been less marked. The saliva had been tested two or three times, chemically and physiologically, and as far as he could make out it was entirely normal. It was of the ordinary specific gravity, slightly reddened litmus-paper, and digested starch about as well as his own.

Dr. Thompson had been undecided whether the salivation was due to the mouth irritation or was the cause of it, but he had about concluded that the irritation was the cause of the salivation. It was not probable that the man had received mercurial treatment. He had thought at one time of a central nerve-lesion. The urine was normal. Oil or vaseline relieved the lips most.

Excessive Salivation for Four Years.—Dr. Charles L. Dana said that last winter there was a woman in his hospital ward who had had excessive salivation about four years. She had entered the ward on account of this trouble, and was then secreting about thirty to thirty-five ounces of saliva a day. While it caused her some annoyance, it did not give rise to the severe burning sensation of which Dr. Thompson's patient complained. He could give no explanation of it, but was inclined at the time to attribute it to a psychical state. The patient was rather feeble in intellect, and one saw now and then, excessive salivation in cases of mental disturbance. She was put to bed, fed pretty well, given atropia up to a tenth of a grain a day hypodermatically, gradually improved, and was discharged as cured after his term of service had expired. The patient's lips had been somewhat swollen, the mouth rather red, the salivary glands were not tender nor swollen. The house physician examined the saliva and said it was normal.

Dr. Francis Delafield said he thought that in Dr. Thompson's case the excessive increase of saliva was secondary to inflammation of the gums and lips. There were really a good many people who had inflammation of the gums and lips which was exceedingly difficult to account for. He had sent some cases of the kind to dentists and to others, and while he had felt that he was himself quite ignorant about the condition, yet he had not been able to find anybody else who knew more than he did. The behavior was more that of a local inflammation than anything else, probably of parasitic origin, although he had absolutely no proof of it. Some of the patients certainly did get well, and entirely well, under treatment by local applications, while others not. But the only thing which seemed to have done any of them any good was local applications. Constitutional treatment had apparently had no influence.

Dr. Delafield said he had long wondered why this matter had not been brought forward into any great prominence by papers or discussions of some kind, for certainly the condition was one which the physician saw every year, and among the best-to-do people, young and old. He had always felt his own complete ignorance regarding it.

Dr. Kinnicutt said that a somewhat similar lesion of the mouth had been described by Dr. Jacobi, under the name of stomatitis neurotica chronica, and by German observers as a tropho-neurosis. Dr. Kinnicutt had seen several cases which resembled the present one, except in the degree of salivation. The symptoms, as a

rule, had been more or less intermittent, but had extended over a long period, and the lesion had caused much suffering. In his experience such cases had proved exceedingly obstinate to treatment of any kind.

Dr. Delafield remarked that some cases, however, did get well. For example, an old gentleman had consulted him about two years ago with sore lips, both upper and lower, and constant flow of saliva. He got well in about two months under local applications made by Dr. Delafield himself, not by the patient. He did not know what was the cause of the trouble, nor, indeed, why it disappeared. Many of the patients had bad teeth, others wore false teeth, which would point to bacteria in the mouth.

Dr. Kinnicutt said he had tried every kind of diet, including that directed against gout, but without apparent effect.

Dr. Robert Abbe thought the history of Dr. Thompson's case was very suggestive of a gingivitis with a parasitic element implanted. Very often a gingivitis started from a very small amount of tartar on the teeth. Add to it a mycotic element, and the trouble might become persistent and aggravated. The salivation seemed to him to be secondary to the irritation of the gums. If the man's teeth were thoroughly cleansed of tartar, and parasiticides were applied around the gums, he would certainly look for improvement.

Morning Diarrhœa.—Dr. Francis Delafield read a paper with the above title (see p. 577).

Dr. Clement Cleveland, in discussing Dr. Delafield's communication, said he had occasionally met with cases of diarrhœa where there were lesions of the uterus and perineum, but not frequently, and in a number there had been relief after operation. He had not studied the cases particularly, but simply remembered that the diarrhœa had been greatly improved after the operation. Usually in displacements of the uterus backward the opposite condition—constipation—was present and it was relieved by pessary or shortening the round ligaments.

Dr. C. L. Dana mentioned one case of morning diarrhœa in particular in which large doses of quinine acted as a specific. In other cases he had known dilute phosphoric acid to prove useful. He could also testify to the value of small doses of castor-oil, which acted favorably in other forms of diarrhœa as well.

Dr. W. H. Draper said he had not infrequently seen all the varieties of colitis, or catarrh of the colon, which Dr. Delafield had described. At least he recognized the varieties. He could not, however, say that he could classify the cases as Dr. Delafield had done. He had seen the different varieties develop in the same patient at different times, mild cases and severe cases. He had been in the habit of looking upon all of them as due to a catarrh of the colon. He thought the nervous symptoms which had been described were very characteristic of this form of catarrh. They were sometimes extremely severe, both with regard to pain and to psychical disturbance.

As to treatment, diet had given him more satisfactory results than drugs. He thought that, as a rule, patients who suffered from catarrh of the colon were persons who were inclined to a diet composed largely of sweets and farinas, and they were relieved by a diet composed largely of nitrogenous foods. He thought the difficulty in carrying out an efficient diet usually was due to lack of directions sufficiently specific in character. The patient might get some relief from cutting off the sweets and starches, and yet feel that he could take fruits, or he might abandon fruits and take starches. But if he would stick to a diet which was absolutely free, if possible, of sweets and fruits, and confine himself to a diet composed of a moderate amount of starchy food, and mainly of nitrogenous food, he would be pretty sure to get relief.

Dr. Draper, said he was not very familiar with the cases which were relieved by gynecological treatment. But even those, he thought, might be aggravated by a wrong diet. There was reason in the dietetic treatment. There was evidence, in the character of the stools and in the distention of the colon with flatulence, of pretty constant fermentation in the large bowel, and this fermentation was certainly kept up more by carbohydrates than by nitrogenous forms of food, and he did not think we could treat them successfully where the cases were severe in any other way than by strict adherence to the appropriate diet.

So far as climate was concerned, this might be sufficient in mild cases, but he could hardly conceive of its being very efficient in severe cases, or cases which had lasted a long time. All were familiar with the effects of a change of air upon catarrhal affections in other parts of the body, and he had no doubt they were efficient also, sometimes, in catarrh of the colon, but for severe cases he did not believe a change of climate or treatment by drugs would be efficient without strict attention to diet.

Dr. Beverley Robinson spoke of a malarial element. For ten or fifteen years he had seen a good deal of diarrhœa in Newport, in both children and adults, which he was unable to check by astringents or by diet, and after many failures he had come to the conclusion that the diarrhœa was only one manifestation of malarial trouble. In one or two instances he had had the blood examined by a capable microscopist who found the malarial organism. In some cases, where quinine had been given without benefit, compound tincture of bark had been curative. Aside from bark, no other drug had been of so great aid as arsenic.

Regarding diet, he had nothing special to add except to state that in speaking of starches as very pernicious, one should be more specific and name the kinds. Dr. Robinson would never allow patients with diarrhœa to eat of potatoes, while he would allow them to eat of rice. There were people who could partake of rice in almost any form with impunity, while they could not partake of potatoes, nor of bread except in certain forms, as dry toast. In his experience dry toast, rice, and nitrogenous food agreed with these patients better than other food.

To eliminate sugar in absolute terms was, in his opinion, a mistake. He believed that there was no better digestive agent to be found than sugar in small amount. Taken in excessive quantity its action was bad. He could recollect as if it were only yesterday having heard Trousseau say to the students that little dishes of sugar would make the gastric juice rich in the stomach, and he believed it.

Dr. Kinnicutt said that while recognizing the different varieties of morning diarrhœa described by Dr. Delafield, and believing that in a large number of cases their origin was to be found in a colitis, at the same time he believed that many of these cases were of the nature of a pure neurosis.

Pure neuroses of the stomach must be admitted, in which there was an increased or diminished secretion of the gastric juice, with hyperacidity or the opposite condition, and it was reasonable to believe that a similar neurosis might affect the intestine, attendant with an increased secretion of the glands, with an exaggerated peristalsis, and even a serous exudation from the vessels. The natural disappearance of all diarrhœal symptoms in certain cases, as the removal of peripheral irritation, such as Dr. Delafield had described, again their disappearance almost directly on a change of climate, even if the journey had been no more than an hour or two, gave support to Dr. Kinnicutt's view. The improvement in the latter case might reasonably be regarded as due to the removal themselves by a changed environment.

Gall-stones.—Dr. Kinnicutt exhibited fifty-nine gall-stones varying in size from 10 × 12 mm. to 7 × 7 mm., which had been passed, per rectum, by a patient in his

ward in the Presbyterian Hospital. The case was one of calculi evidently impacted in the common duct. There were the physical signs of a dilated gall-bladder, also the symptoms of obstructive jaundice, and evidence of the existence of a catarrhal cholangitis in an irregular fever of very considerable degree, at one time reaching 106° F., chills, etc. He had advised surgical interference, but in the meantime phosphate of soda, and six to eight drachms of glycerine were given daily to the patient. Suddenly, with a violent paroxysm of hepatic colic, a large stone was passed per rectum, and in succession, during the ensuing forty-eight hours, fifty-eight additional ones. There was constant pain during this period, which abruptly ceased toward its close. Shortly after the detection of the first stone the stools became normal in color. It was possible that the calculi had escaped by ulceration into the intestine, but the symptoms taken collectively pointed rather to a passage through the duct. Dr. Kinnicutt was inclined to be sceptical of any effect of the phosphate of soda and glycerine in promoting the elimination of the calculi.

Acute Biliary Colic and Jaundice due to Tumor of the Pancreas.—Dr. Robert Abbe related the case of a patient who for months before he saw him had been having attacks of apparently biliary colic attended by jaundice. He had lost thirty pounds and was in low condition. When first seen by Dr. Abbe there was jaundice and pain, but without distention of the gall-bladder. Believing, however, from the history that there was an impacted stone, or several small stones, he made the usual exploratory incision. The gall-bladder was not found distended, no stones were felt, nothing was found to account for the symptoms except tumor of the head of the pancreas as hard as a raw potato. Anastomosis was established with some difficulty by Murphy's button between the gall-bladder and duodenum, and the patient made a good recovery. The hardness in the pancreas was suggestive of malignant disease. Dr. Abbe had always supposed that malignant disease in this situation caused slow and painless jaundice, whereas in this case the attacks were acute and painful, like in ordinary biliary colic.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE OFFICIAL REPORT ON THE CHOLERA IN 1893—TENURE OF OFFICE OF MEDICAL OFFICERS OF HEALTH—CHANGES IN THE INSPECTORSHIP—THE TUBERCULOSIS COMMISSION—SMALL-POX—DEATH OF MR. SHIPTON.

LONDON, April 20, 1895.

"CHOLERA in England in 1893" is the subject of Dr. Thorne Thorne's Report to the Local Government Board. This report, which has just appeared, has been expected by sanitarians with no little interest, and as the expression of the head of our sanitary department must exercise great influence. Dr. Thorne divides the report into three portions, viz.: The local manifestations of cholera in England, bacteriological study of the disease, and the diarrhœal outbreak at Greenwich. All these were duly chronicled by me at the time, but it will interest your readers to mention a few points now authoritatively given. The report itself will be of great use to sanitarians and all interested in the subject; it is freely illustrated by maps and plates; shows the great value of the measures adopted to resist invasion, and affords fresh proof of the effects of sanitary foresight. No less that sixty-four districts were actually invaded, and in forty-two of these only a single case occurred. The total number of attacks reached two hundred and eighty-seven, of which one hundred and thirty-five died. The disease first gained its footing at Grimsby and Hull, and the maps show that the majority of localities invaded lie within an angle with its apex at the mouth of the river Humber and the sides running northward to York and southward to Leicester. Whether the disease was due to a recrudescence from the previous year or to fresh invasion from the continent is not decided by this report. The first cases were imported in June, but from them the disease did not spread. In August came the Grimsby and Hull outbreaks. There was ample opportunity for entrance at those places, and Dr. Thorne thinks that probably the disease had acquired a footing there some time before the fact was recognized. An immense influx of excursionists was going on at the time and the drainage was faulty, but the water is reported to have been good. The question of oyster contamination occurs here. The oyster-beds are admitted to be liable to be washed by sewage. Both oysters and mussels from these localities are largely consumed uncooked, and it is difficult to shut one's eyes to the danger, which is admitted in the report, although in the most cautious manner. The lessons to be learned from the report are many, the most satisfactory being that our English sanitary work has abundantly repaid us the great cost, and that the methods adopted for preventing invasion have been more efficient than any other system. Our sanitary administration maintained its repute at this trying period and has earned our confidence.

The question of the tenure of office of medical officers of health calls for legislation. In many cases the appointment has been annual, and re-election each year has been looked upon as a mere formality. But recent instances show that the officer is by no means secure and may be got rid of should he happen to offend some of the members of his board. As these may be owners of insanitary properties the position is awkward and may easily become untenable. Recently an officer of nearly twenty years' service retained his post only by the casting vote of the chairman. Something should be done to maintain the independence of these officers and give them fixity of tenure.

Dr. Hubert Airy has been obliged to resign the medical inspectorship of the Local Government Board on account of ill-health. Dr. Seaton Buchanan, the son of Sir George, has been appointed to the position.

The report of the Royal Commission on Tuberculosis has been agreed upon and will be presented to Parliament within the next few days.

Small-pox has continuously declined since my last reference to the subject. There have only been twenty-five new cases in the last three weeks and none of them proved fatal. Last Saturday there were not fifty cases remaining under treatment. From the provinces also the news is favorable.

Leicester, the home of anti-vaccination, has actually established a bacteriological institute under the direction of its medical officer of health.

Among recent deaths I would name, with much regret, that of William Parker Shipton, of Buxton, at the age of seventy-seven. He passed most of his life at the important northern spa, and will be remembered by numerous travellers as well as patients. He was consulting surgeon to the hospital in which so many chronic rheumatics were relieved and to which his son is surgeon. He was also a justice of the peace for Derbyshire. Invalid visitors to Buxton will certainly miss his genial presence.

Cremation in Italy.—The number of crematories in Italy in 1894 was 23, and there were 2,509 bodies cremated. Although Italy was one of the first countries to agitate the question of cremation as a substitute for earth burial, the reform has not made very rapid progress, owing to the hostility of the Church.

UPON TRANSPLANTING TESTICLES.

To the Editor of the Medical Record.

Sir: I have read with interest the report of the meeting for April 8th, of the Surgical Section of the Academy, and regret that I could not have been present during the discussion of Dr. Walker's interesting paper upon undescended testis. Allusion was made to attempts to draw this organ down into the scrotum, and to other operative plans, both when, as is the rule, hernia accompanies this condition, and when the retention of the testis in the canal is alone the abnormality. But none of the speakers alluded to a plan which I had the honor to suggest years ago, and which may be found in my article upon hernia in Wood's "Reference Handbook," vol. ix., page 415.

I refer to the very simple and safe procedure of placing the organ in the loose cellular tissue behind the inguinal canal, and leaving it there, no longer subject to the painful pressure which must be the case when the testicle lies in the canal, subject to muscular contraction; and driven between unyielding aponeuroses.

It is not invariably the case that an undescended testicle is sterile, and even if it were, many patients, as a matter of sentiment, prefer to keep it, rather than have but one. And when we consider the difficulty and frequent failure of the ordinary plan—that of endeavoring to stretch the cord, dissect up, partly, the epididymis, and otherwise induce the testicle to enter the scrotum, and then to keep it down there, this plan to which I allude is beyond comparison easier.

It is the belief of the writer that in this device will be found a great advance in the treatment, also, of inguinal hernia in the male, operated upon for radical cure by whatsoever method.

Let us consider a little. What is the weak spot in the perfection of any and all of the twenty or so modern plans which I have recently written up in this article just alluded to, upon radical cure of hernia?

It is the fact that by any—even that of Bassini, which I think commonly the best—we still have instead of a solid abdominal wall, a wall with a hole through it, for the spermatic cord to traverse. This cannot be a tight-fitting canal, either, or we produce varicocele. Being moderately loose, it to a certain extent invites a return of the hernia, upon the wedge principle.

Dr. Halsted, recognizing this fact, has in the plan of operation which bears his name, advocated always reducing the size of the cord (and hence the calibre of the canal) by cutting away three-quarters of all the pampiniform plexus of veins, and leaving enough, barely, to permit exit of blood from the testicle.

If, now, it is sound sense to try to make this canal small, a little further application of common sense shows us that it would be better still to have no canal at all; to have as solid and firm a belly-wall here as anywhere else, instead of a wall with a hole through it. And that is exactly what I am advocating.

To accomplish it adds not two minutes by the watch to the operation, nor any danger. There is nothing easier. Let us suppose that the usual steps in a Bassini operation have been gone through, up to the point where the conjoined muscles—internal oblique and transversalis—having been stripped bluntly and freely from the external oblique above and the fat and fascia beneath, are about to be stitched to Poupart's ligament, thereby making a strong muscular rear wall to the inguinal canal instead of the weak one supplied by Nature.

At this point in the operation, before doing this sewing, let us simply strip the transversalis even more freely beneath with the finger, so that a space is left between muscle and peritoneum into which a small orange could be placed without being subjected to pressure. Now draw gently upon the spermatic cord, until the testis is brought forth from its bed in the scrotum. Anyone who has tried this knows that it is but the work of a moment, without any trouble, and then, with a snip of the scissors the cellular attachment of the testis to the bottom of the scrotum is severed. The cord is now neatly wrapped around the testicle, to prevent kinking and hence obstructed circulation, and both cord and testicle are placed in the comfortable bed prepared for them, as already described. Now the ordinary steps of the Bassini are resumed, and the muscles sewn to Poupart's ligament, and next the split external oblique aponeurosis is united, and so on. But, observe, there is now left a solid wall, and no inguinal canal or rings at all to invite a return of the hernia.

For all practical purposes that testicle is as good as ever. Simply, it is taken out of the cold world and its possible buffets, and transformed into an ovary.

As to the question of function, I fail to see the slightest reason why the testis so placed should differ from one in the scrotum. Let no one compare it with the ordinary undescended testis, so commonly sterile and painful. The latter lies in the inguinal canal, subject to firm unyielding pressure on all sides; a most uncomfortable place. Whereas, it must be noted, our transplanted testicle is behind the real abdominal wall, and is not subject to pressure in the least. It has nothing but fat, fascia, and peritoneum between it and the bowels. And its own coiled-up cord, encircling, still further protects it.

It would be unwise to place it within the actual peritoneal cavity, both because there might be adhesions between it and the bowels, and because of the well-known absorbent and digestive action of the peritoneum. For this last reason one would naturally expect what a Scotch experimenter proved true some three years ago: that testicles placed within the peritoneal cavity shrink and atrophy more or less in the case of dogs.

The writer would not venture to offer this plan to medical men, however attractive it is logically, had he not tried it repeatedly (now six times) within the past few years. And in no case has there been complaint of any discomfort in the new ovary, nor (so far) a return of the hernia.

It will be obvious that the patient's consent must be gained; but when the advantage is explained, that should not, as a rule, be difficult. It is very different from advising castration, with the same object in view.

One objection has occurred to me as worthy of thought: namely, what if the patient shall at some time subsequently develop epididymitis on that side, after gonorrhœa or otherwise? This complication would, I think, be less apt than usual to occur, because of the testicle being so well elevated. We all advise the suspensory bandage in gonorrhœal cases, with this thought in mind. But if the epididymitis should actually occur, then a very fair plan of treatment of the testis in the scrotum would be equable, gentle pressure, support, elevation, and poulticing (heat and moisture). And all of these the swollen organ would assuredly find in its new position, without our having to do more than relieve pain by drugs.

However, if it be admitted that our patient with hernia will probably have his chances of permanent cure bettered by transplanting testicle and cord, I hardly think the consideration of a possible outcome of a possible subsequent venereal disease should cause us to vote against the operation.

In conclusion, it is of course well known that certain other efforts have been made to close absolutely the inguinal region. Several are described in the article upon radical cure of hernia already mentioned (Wood's "Reference Handbook"). Of these, Halsted's and Frank's are the most original. The former, as stated, reduces his cord about three-fourths in size. He drags it out toward the anterior superior iliac spine, making a new deep ring farther outward than natural, and sews the inguinal region solidly, conducting the cord just be-

neath the skin and superficial to the muscles from the new deep ring to the scrotum. But after all is done, he has still an inguinal ring instead of an absolutely solid wall. Moreover, surgeons doubt whether so great a reduction in the number of spermatic veins as a sacrifice of perhaps three-quarters is desirable for the welfare of the testicle.

As to Frank's plan (described in Billroth's jubilee volume), it consists in chiselling out of the horizontal ramus of the pubes a deep gutter, through which the spermatic cord is run. Then the inguinal canal is obliterated, with its rings, by sewing all solidly together. The plan is ingenious, but certain theoretical objections, such as callus pressing on the cord, are obvious.

It is my hope that this letter may be the means of inducing others to give a trial to the transplantation plan advocated. Both in radical cure of hernia and in painful undescended testis it seems to the writer well worthy of thought. Very respectfully,

ROBERT H. M. DAWBARN, M.D.

NEW YORK, April 27, 1895.

HOW THE VALUE OF ANTITOXIN IS DISTRUSTED BY SOME OF THE VERY MEN THAT ADVOCATE ITS USE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: To go through medical literature, and point out to the readers of the MEDICAL RECORD under what circumstances antitoxin has been used as a remedy in diphtheria, I will not venture to do. The task to be accomplished requires more of your valuable space than I desire to take up by this letter. I wish simply to call attention to facts which may be verified by reading the April numbers of your journal.

Therein, one finds articles on the therapeutic value of antitoxin with clinical reports. These articles have all been titled and clothed in such a manner, as to lead the credulous to believe that all the results obtained were only due to this remedy. However, as we peruse more carefully, we find in addition to the hygiene, careful nursing, and watchfulness of the attendants, quite a number of remedies used in conjunction with antitoxin.

For examples: Dr. Cyrus Edson used gray powder, sprays of Dobell's solution every two hours, sodium bromide, and two drachms of whiskey every three hours.

Dr. Joseph S. Healey says: "Of fourteen cases of true diphtheria, I used the antitoxin treatment in but three, but did not dare trust to it alone."

Dr. J. C. Davies, in a report of twenty-one cases, says: "In all cases where the disease had made any considerable progress before the administration of antitoxin alcohol stimulants, together with iron and quinine, were given in connection with it."

Dr. Valentine Brown, in a report of thirty-four cases, used in addition to the serum, in the majority of his cases, stimulants, brandy, whiskey, digitalis, nux vomica, iron, turpeth mineral, antiseptic lotions and, what he calls, "the usual remedies."

As scientific therapists can we attribute all virtues to one remedy when used in conjunction with others? Does not the very fact that others must be used show its weakness, and the distrust of the authors to it alone?

WILLIAM JACOBSOHN, B.S., M.D.

152 EAST EIGHTY-SIXTH STREET,
NEW YORK, April 29, 1895.

An Old Gentleman, one hundred and two years of age, living in Maine, recently fell, as he was preparing to shave himself, and fractured the neck of the femur. He claimed that he had not had to seek medical aid before for eighty years.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 4, 1895.

	Cases.	Deaths.
Tuberculosis	191	130
Typhoid fever	9	6
Scarlet fever	108	15
Cerebro-spinal meningitis	4	5
Measles	255	22
Diphtheria	223	44
Small-pox	1	0

Cheap and Handy Applicators.—Dr. John Winslow, of Ithaca, N. Y., says that the best short cotton applicators are the common four-sided, double-pointed, hard-wood tooth-picks, costing five or ten cents a thousand. The best long ones, for most purposes, are made of iron wire, flattened with a hammer at the distal end and bent into a ring handle at the proximal. The wire should be flexible enough to be easily shaped by the fingers after winding, and stiff enough to retain the shape so given. Such wires, made by the tinsmith at a trifling cost, may be thrown away after once using, or may have the cotton burned off and be used again. They cannot, of course, replace the flat silver applicator where great pliability is required.

Female or Woman.—Dr. Howard A. Kelly writes as follows to the editor of the *American Journal of Obstetrics*: "A good friend with a fine English sense who occasionally looks over my shoulder as I write, left this note ('Female' or 'Woman'?) pinned to one of my papers a few days ago. I think the fault common enough to be worth while correcting publicly. And as it is manifestly an error to which a gynæcologist is more prone than other men, the correction ought to appear in the *American Journal of Obstetrics*: 'Take care not to use the word "female" as meaning a woman. It is correct to speak of the female pelvic organs, but a "female" is not a woman; it is a cow, a mare, any animal of the female sex. It is old-fashioned English to call women females, and the expression is coarse in this sense.'"

Lady Doctor or Physicienne.—A weekly penny paper called *Answers*, which is said to circulate by the million, suggests "Physicienne" as a title for female members of the medical profession, by way of an alternative for doctora, doctorina, and other equally euphonious designations. Perhaps the suggestion is intended as a witticism, for the journal aims, not very successfully, at facetiousness, but if so we question whether the real point of the joke will be apparent to the majority of readers. The meaning ordinarily attached to the word "physicien" in French is conjurer or mountebank; a man who extracts teeth *coram populo*, makes omelets in a hat, or produces endless lengths of ribbon out of his mouth; and although the feminine inflection is absent from the dictionary, "physicienne" can only be regarded as standing for the female of that ilk.—*Provincial Medical Journal.*

The Poultice has recently been examined bacteriologically by Dr. R. W. Lovell, and he happily finds that it is reasonably sterile and non-pathogenetic. It would be hard, indeed, if the soulless searchers after microbes were to lay the ban upon this most comforting and useful domestic remedy. How few mortals pass through this vale of tears without the occasional solace of hot pultaceous flaxseed. As long as there are boils there will be poultices to solicit the streptococci into gentler activity.

ERYSIPELAS TOXINS AND ERYSIPELAS SERUM IN THE TREATMENT OF INOPERABLE MALIGNANT TUMORS — FURTHER OBSERVATIONS.

BY WILLIAM B. COLEY, M.D.,

ATTENDING SURGEON TO THE NEW YORK CANCER HOSPITAL; ASSISTANT SURGEON TO THE HOSPITAL FOR RUPTURED AND CRIPPLED, NEW YORK.

SINCE the publication of my last paper[1] I have had a number of results of the highest importance not only as confirming the conclusions already expressed, in regard to the curative influence of the toxins upon sarcoma, but also as fulfilling, in a measure, at least, the prediction then made, that in time we might expect similar results in carcinoma. Moreover, with the aid of Mr. B. H. Buxton, assistant pathologist to the New York Cancer Hospital, a very important modification in the method of using the erysipelas has been worked out, and one that promises to be a great improvement over the earlier methods.

This improvement consists in first subjecting animals to the action of the erysipelas for a time, and then employing the blood-serum of such animals instead of the toxin directly. This does away with the severe reactions and depressing effects that follow the injections of the toxins. The only question which remains to be determined by further experiment is the relative value of the serum and the toxins. In the fall of 1894 Mr. Buxton, in conjunction with Dr. Emil Schmitt, began to immunize a horse to erysipelas, giving constantly increasing doses of virulent cultures of erysipelas, sterilized cultures and bacillus prodigiosus prepared in the same way as I have already described when used for sarcoma.

After the horse had been injected for six weeks, and was able to withstand very large doses with little effect, he was bled, and the serum was placed in small, glass-stoppered bottles and kept in the dark. This serum I have employed upon eleven cases—two very large and advanced cases of inoperable carcinoma and one case of large malignant tumor of the neck, with secondary involvement of the sternum (probably carcinoma), and one of recurrence of carcinoma of the breast.

CASE I. *Recurrent Carcinoma of the Breast.*—The tumor was a rapid recurrence from a primary cancer of the breast, and was situated in the middle of the sternum, and apparently connected with the sternum itself. This case had been treated for several weeks with the toxins without any perceptible decrease in size, although growth had evidently been checked. The injections of erysipelas serum were begun in January, 1895, and continued for two weeks. ℥v. was the largest dose employed. There was no apparent effect on the tumor.

CASE II.—The second case was the largest carcinoma of the breast that I have ever seen. The patient was a woman, fifty years of age, with a history of the growth having appeared about two years before. There had been no operation, and when I first saw her the entire right breast was involved, forming a perfectly symmetrical spherical tumor the size of a two-quart measure, and very protuberant. The semicircumference was eleven inches. The axillary glands were not involved, and there was no swelling of the arm. The tumor was firmly fixed to the chest-wall, and extended from the axillary line to the middle of the sternum, and from the clavicle nearly to the free border of the ribs. The skin over it was closely adherent, and ulcerated over a small area below the nipple. A section was removed and proved to be carcinoma on microscopic examination. The patient's general condition was fair, and she showed little emaciation. The injections of the erysipelas serum were begun February 7, 1895, starting with one minim, and gradually increasing up to twenty. No chill and no reaction followed, but a slight faintness was observed in this as in one of the other cases. The effect upon the tumor was apparent within a few days. The skin over the tumor became less tense, the tumor itself became more movable, and perceptibly smaller. The injections were kept up for several weeks, and the improvement continued. I then substituted the toxins for the serum to compare the relative effect. The tumor steadily shrank in size, and its mobility increased. The toxins were given in large doses (℥ iij. to vj.) which caused a reaction temperature of 104° to 105° F., and the patient showed the effect of the depressing action; still she was up and about the ward every day. The area of ulceration became deeper, and masses of tumor-tissue of considerable size sloughed out at this point.

In April, 1895, the tumor was less than one-half its original size, but, unfortunately, the sloughing had caused an erosion of a blood-vessel of considerable size, and set up hemorrhage that could not be controlled, resulting in death. Autopsy showed the pleura, pericardium, and suprarenal capsules to be carcinomatous. I had never had any hope of a cure in this case, but the striking beneficial effect of the injections in such a case where the diagnosis is established not only clinically and microscopically, but confirmed by an autopsy showing metastases, cannot but be regarded as very strong evidence of the value of both the serum and the toxins in carcinoma.

CASE III. *Probable Carcinoma of Neck and Sternum.*—The growth, which had before been increasing rapidly, ceased to grow, became less fixed, and slightly smaller. In this case urticaria, similar to that described after the diphtheria antitoxin, was observed after some of the injections. In this case, as in Case I., no bad symptoms followed, and the injections caused much less pain than when the toxins were used. This patient is still under treatment at the Cancer Hospital, and the tumor is slightly decreasing in size. Treatment with erysipelas serum begun February 7, 1895.

The remaining cases are recent cases, and it is too early to speak of results.

The doses have not yet been pushed to anything like the probable limit of safety, but the first supply of serum failed to keep well, and only recently has a new supply been secured. This has been made from the blood of a horse that Mr. Buxton had injected for two months with mixed toxins of erysipelas and bacillus prodigiosus. I am now using it on eight cases, four of sarcoma and four of carcinoma, and shall endeavor to determine whether or not it is superior to the toxins used directly. I am giving it in much larger doses and it causes no bad symptoms. If it proves superior to the toxins, as there seems reason to believe it may, a very

[1] MEDICAL RECORD, January 19, 1895.

great step in advance will have been made, inasmuch as the chill and severe reactions, with their consequent depressing effects, will have been done away with. This view is strongly confirmed by the very recently published paper of Professor Rudolph Emmerich and Dr. Hermann Scholl.[1] Their experiments with the erysipelas serum were begun last December, about the same time as my own, though quite independently, and as their cases treated with the serum throw so much additional light upon this most important subject I have thought it of interest to give a full translation of the cases, with a *résumé* of their paper. Before doing so I wish to give a very brief report of my own recent results in epithelioma.

Case I. *Epithelioma of Chin, Lower Jaw, and Floor of Mouth—Inoperable—Apparent Cure.*—This case was reported (*loc. cit.*) as probably only temporarily improved. It is a very important case since it is the first success I have had with epithelioma. The patient, female, aged thirty-four, was admitted to the Methodist Episcopal Hospital in May, 1894, with a rapidly growing epithelioma, involving the central portion of the lower jaw, the floor of the mouth, and all of the softer structures of the chin. There was an area the size of a silver half-dollar, the site of a typically epitheliomatous ulcer. Microscopic examination showed the growth to be epithelioma.[2] Dr. George R. Fowler, in whose service she was, considered the case inoperable and kindly referred her to me. She was under treatment at the New York Cancer Hospital for about ten weeks, during which time the mixed toxins of erysipelas and bacillus prodigiosus were injected into the chin at intervals of twenty-four to forty-eight hours.

As I stated before, the improvement was immediate and remarkable. At the end of two weeks the ulcer had nearly healed and in three weeks it had entirely healed, and the parts had nearly regained their normal appearance. Later on there was an apparent change for the worse, and two small ulcers, about one-fourth of an inch in diameter, reappeared at the site of the original large ulcer. The patient's general condition became impaired from the long-continued injections, and I decided to abandon the treatment for a time the latter part of September, 1894. She went to her home, and the only treatment she has since had has been the administration of tonics and local application of electricity for a time to the small ulcers of the chin. I saw her May 3, 1895, nearly eight months since the injections were discontinued. I could find no evidence of the cancer remaining, and the skin over the chin had regained nearly a normal appearance, and was soft and pliable. Her general condition seemed perfect, and she stated that she never felt better.

Case II. *Recurrent Epithelioma of the Face.*—The patient, aged forty-five, male, had a small recurrent epithelioma of the face involving the lower eyelid. The primary tumor I had removed by operation, at the New York Cancer Hospital, eighteen months before, and microscopic examination proved the growth to be epithelioma. I treated the recurrent tumor at the hospital in February and March, 1895. The growth apparently entirely disappeared, and the patient has returned to work.

Case III. *Epithelioma of the Tongue—Inoperable.*—The patient, a woman, aged forty-nine, had first noticed an ulcer on the right side of the tongue five months before.

In February, 1895, she consulted Dr. F. Lange, of New York, and he regarded the growth as inoperable. Fully one-half of the tongue was involved, from the tip to the base, and the whole tongue was so bound down to the floor of the mouth that the tip could not be projected beyond the line of the teeth. I removed a portion of the growth, and it was pronounced "typical epithelioma" by the pathologist of the New York Cancer Hospital, Dr. E. K. Dunham. After two weeks' treatment with the mixed toxins the growth had so far diminished and the tongue had become so much more movable that it could be projected one inch beyond the incisor teeth.

The treatment was continued two weeks longer, but with no further improvement. Although a failure as far as a permanent result is concerned, this case is of importance since it proves the marked antagonistic and destructive influences upon a very advanced case of indisputable epithelioma.

The following is a report of Professor Emmerich's results with *erysipelas serum*.

Clinical Experiments on the Cure of Cancer by Means of Erysipelas Serum, by Professor Rudolph Emmerich and Herman N. Scholl, M.D.

After describing the experiments by which Emmerich proved that when an animal was inoculated with erysipelas, his blood-serum is curative for anthrax, the author continues:

"After it became known[1] that natural and artificial inoculation with erysipelas would cure cancer, it was a slight step to suppose that this cure is produced, even as the cure of anthrax is produced, by changes which the erysipelas cocci produce in the blood. If this natural conclusion were right, then the blood-serum from an animal inoculated with erysipelas, when freed from its erysipelas cocci, must be a cure for cancer just as well as for anthrax. The conclusion from the analogy is inevitable that the curative serum injures the cancer parasites just as it cures anthrax by killing the anthrax bacilli."

It was found that serum from inoculated sheep was more powerful than from the other animals experimented upon. "The preparation of the erysipelas serum is much more difficult than the preparation of serum for diphtheria. It is necessary to observe numerous precautions, and only certain races of sheep must be employed to obtain a really efficient serum. . . .

"The preparation of the serum is as follows: The sheep which has been inoculated with erysipelas is bled to death, and the blood caught in sterile glasses. After a certain time the serum is removed by pipettes and freed from erysipelas cocci by filtration through a Chamberland or d'Orsonval filter. The serum, which is by these means sterilized without heat, is placed in test-tubes of 10 c.c. each, sealed and preserved in the dark.

"With this erysipelas serum we have treated, in the past six months, a number of cases of carcinoma and sarcoma. In only two cases did it have no effect whatever, and these were cases in which secondary nodules and gangrenous degeneration were present. In the future such cases will not be treated with the serum, as such a condition will be prevented by the earlier use of the serum.

Case I.—"Complete or at least temporary cure was accomplished in the case of Marie H——, aged fifty-four, in whom a total absorption of the carcinoma nodules was accomplished, and up to to-day no recurrence has taken place.

"The patient was sent to us by Professor Angerer as an inoperable case. Two years before the right carcinomatous mamma was excised. In the course of a year following this operation, the patient had two apoplectic attacks, resulting in right-sided paralysis of the extremities and interference with speech. December 14th there existed in the pale skin of the greatly ema-

[1] Deut. Med. Woch., April 25, 1895.

[2] Pathologist's report: "Material from chin and lower jaw (May 20, 1894). Sections were not entirely satisfactory, but from gross appearance of the materials and those revealed by the microscope the diagnosis of epithelioma is offered." Signed (Belcher). This report has just been sent me by Dr. Fowler. A former letter stated the diagnosis as "epithelioma," without qualification. That it was epithelioma or sarcoma, the clinical history and appearance alone, which were so characteri tic, render doubt scarcely possible.

[1] W. B. Coley: Treatment of Inoperable Tumors. American Journal of the Medical Sciences, July, 1894.

ciated patient, near the operation scar, a hard nodule the size of a pigeon's egg, and a nodule as big as a hen's egg in the right axilla. The skin over the globular nodules was tightly stretched, and a shiny dark red. The entire infraclavicular region above the pectoral muscle was hard as a board and infiltrated with carcinoma, and from this area of infiltration, as big as a saucer, a fistula led into the axilla, where it discharged purulent fluid through an opening as big as a silver half dime. Above the right clavicle in the neck were to be felt one gland as big as a walnut and several as large as hazel nuts. The right arm was markedly œdematous and wholly useless.

"*After only two injections of the erysipelas serum of 0.5 c.c. each, made on two succeeding days, into the nodule the size of a pigeon's egg, this nodule was reduced to one-half its former size, and the skin, which before was tightly stretched over it, became loose. On the third day, after the injection of altogether 2 c.c. of the serum, this nodule has disappeared entirely.* In the meantime daily injections of small quantities of serum (0.5 to 2 c.c.) were made into the nodule the size of a hen's egg, and into the hard infiltration under the clavicle (1 to 1.5 c.c.). The latter diminished so after two injections that it could no longer be felt. On December 18th the hitherto greatly swollen arm was of about the same size as the left, and the patient, who for six months had not been able to move this arm, was delighted 'to be able once more to cross herself and lift her spoon to her mouth.' Over the hen's egg nodule proceeding from the fistula there was fluctuation. An incision 5 ctm. long passed in part through the carcinomatous nodule. A couple of drachms of pus escaped, from which the staphylococcus aureus was developed upon gelatine plates.

"The injections of small amounts of serum (0.5 to 2.0 c.c.) were continued, but not daily, until January 4th. By January 8th the hen's-egg nodule in the axilla had entirely disappeared, and the incision as well as the fistula was completely healed. The right arm was freely movable, and by a simple motion a fracture of the clavicle resulted—a sign that the carcinomatous masses which surrounded the carcinomatous degenerated clavicle were absorbed and the clavicle was deprived of its former support; the glands in the neck could scarcely be felt, and the patient left the hospital January 12th temporarily cured, to return home. This almost complete cure was accomplished from the injection of only 40 c.c. of serum altogether. The doctor who had charge of the case in her home (Dr. Ludwig Krieger), wrote us on February 21st that the patient was troubled with insomnia but was otherwise well. The general condition was good, the fracture of the clavicle was completely healed, and up to date there was no recurrence of the carcinoma.

Case II.—"The second case, also furnished by Professor Angerer, was an exactly similar recurrent carcinoma after excision of the left breast. Along the scar of the operation there were three hard nodules in the skin from the size of a pea to that of a cherry, and a fourth one as big as a hen's egg in the scar. In the course of a week the patient received daily injections of 0.3 to 0.5 c.c. of the serum in the various nodules. In this short time the smaller nodules entirely disappeared, but the great one was not reduced at all in size; unfortunately the patient left the hospital at this time as she was unable to pay her board longer."

Case III.—The third case mentioned, one of ulcerating carcinoma of the mamma with metastases in the liver, was not treated by the author, and the serum injections were made only occasionally and in small amounts (30 c.c. in all), but in ten days one small nodule had entirely disappeared and others had diminished at least two-thirds in size.

Case IV.—"The fourth patient was a lady in Baden-Baden, also a case of recurrent carcinoma after excision of the mamma. A year and a half after operation a carcinomatous nodule as large as a nut had formed in the inner surface of the upper arm in the skin. In fourteen days after the injection of 20 c.c. of serum this nodule had disappeared, but the injections were continued in order to prevent a recurrence.

Case V.—"A woman, aged thirty-four, with hereditary predisposition, presented a large carcinoma of the right mamma, and a gland in the axilla as big as a goose egg. Since October, 1894, the patient had noticed an increase in size and hardness of the right breast, which did not disturb her, as she was pregnant. January 26, 1895, she was delivered; but the breast continued to increase and grow harder, and on February 23, 1895, she began treatment with us. The breast measured 17½ ctm. vertically; 18½ ctm. from right to left. On February 23d, 2 c.c., on the 24th, 4 c.c., and on the 25th, 11 c.c. of the serum were injected into various parts of the tumor. On February 26, 27th, and 28th, 5 to 6 c.c. were daily injected, and on March 1st, 11½ c.c.

"March 5th.—No further injections having been made, the tumor measured 15 ctm. from above downward instead of 17½ ctm.; while the lateral measurement had shrunk from 18½ ctm. to 16½ ctm. March 4th, 2 c.c. serum were injected into the goose-egg axillary gland and 5 c.c. into the mamma. March 7th, 12 c.c.; March 8th, 8 c.c. serum injected into the tumor. On March 11th, the tumor measured 14 ctm. in each direction; a diminution in circumference of 8 ctm. The goose-egg gland in the axilla was reduced to one-half its former size or less. From lack of serum no more injections were made until March 20th, when 0.5 c.c. was used; March 21st, 2 c.c., and March 22d, 4 c.c. in different parts of the tumor.

"That is indeed a remarkable result, when a tumor which formerly was rapidly growing is after such a short treatment not only stopped in its rapid growth, but actually reduced so much in size! Further the previously board-like carcinomatous tissue has become much softer. While at first the injection required great force, it can now be made as into normal tissue.

Case VI.—"The sixth case was one of epithelioma in a woman, aged sixty-five, with hereditary predisposition. For nine years the patient has had a tumor in the outer canthus of the left eye, rapidly growing during the last year. In the left outer canthus is a globular nodular tumor 3 ctm. high and 2 ctm. broad, and presenting a small ulceration. Extending from this point across the upper lid is a cylindrical process which has an ulcer on its extreme end. A similar process extends the length of the lower lid. In the orbital subcutaneous tissue above the outer end of the upper lid can be felt a tumor as big as a cherry pit, extending into the deeper tissues.

"After four daily injections of 2 to 3 c.c. each of the serum, the tumor in the outer canthus had completely flattened and degenerated. The cylindrical tumor of the lower lid had completely disappeared. The injections were continued, small amounts (0.5 to 2 c.c.) being used with frequent intermissions (as long as fourteen days). At present the whole tumor has degenerated, and in place of carcinomatous tissue there exist ulcers which appear to be healing. The tumor in the subcutaneous tissue of the orbit can no longer be felt. On the other hand, a growth scarcely as large as a split pea has developed in the ulcer of the upper lid. There is a reasonable ground for belief that this case can be cured by further injections of the serum. This belief is justified by the fact that the ulcer which followed the degeneration of the large tumor has already partly skinned over, and has partially cicatrized along the canthus. But this case requires a further carefully continued treatment. It appears from this that very old carcinomata or epitheliomata recover by degeneration of the carcinomatous tissue and subsequent cicatrization, while younger carcinomata, as we have seen, simply disappear by absorption, and indeed more rapidly the younger they are. . . .

"The description of the cases treated by the serum

proves that it merits the name of a specific for cancer. According to Coley's observations it is probable that erysipelas serum works more effectively against sarcoma than carcinoma. He has found the spindle-celled and mixed varieties most favorable for treatment, while round-celled and osteo-sarcomata are not so susceptible.

In the smaller tumors 1 to 4 c.c. were injected daily. In the larger ones 10, 15, 20, or even 25 c.c. were injected in various parts at once.

"Small doses (5 c.c.) produced no pain. After repeated injections there was a light 'drawing' pain, lasting only a few hours, even after injections of 10 to 20 c.c. In no case was the pain sufficient to require medicine.

"In most cases there was no fever. In no case did the temperature exceed 39° C. (102° F.). No patient complained of headache, anorexia, etc., as a result of the injections. On the contrary the favorable effect of the serum on the general condition of the patients was very striking.

"After the injection of small doses of an active serum, either at once or after a few hours, there appears a false erysipelas, an aseptic erysipelas consisting of more or less swelling of the skin with slight redness. The degree of redness is always less than that of true erysipelas. This erysipelatous swelling extends beyond the limits of the tumor, but naturally does not spread of itself and disappears entirely in twenty-four or forty-eight hours after the injections are discontinued. The stronger this pseudo-erysipelatous swelling, the better is usually the curative effect of the serum.

"Coley's investigations along similar lines have proved that we possess in erysipelas serum a specific for cancer; but we stand yet simply at the beginning of the methods of treatment and that should not be forgotten. Especially must we endeavor to isolate the actual effective substance so that it can be given in determined and when necessary in large doses."

DOUBLE CASTRATION FOR HYPERTROPHY OF THE PROSTATE GLAND—REPORT OF A CASE.[1]

By JAMES R. HAYDEN, M.D.,

CHIEF OF VENEREAL CLINIC, COLLEGE OF PHYSICIANS AND SURGEONS (COLUMBIA COLLEGE); PROFESSOR OF GENITO-URINARY AND VENEREAL DISEASES, MEDICAL DEPARTMENT OF THE UNIVERSITY OF VERMONT; VISITING SURGEON TO THE CITY HOSPITAL, NEW YORK.

THE therapeutic value of castration for hypertrophy of the prostate gland was suggested to the profession by J. W. White, of Philadelphia, in a paper entitled: "The Present Position of the Surgery of the Hypertrophied Prostate," which appeared in the August number of the *Annals of Surgery* for 1893. In this article Dr. White showed conclusively, by control operations on the dog, the rapid atrophy of both the glandular and muscular elements of the prostate, following double castration. I will not occupy your time with a review of the cases so operated on, and reported, since that date, but refer you to the appended bibliography.

The history of my case is as follows:

Mr. X——, seventy years of age; married; dentist by profession. The patient has never had any venereal or genito-urinary disease, and has always been most temperate in his habits. Five years ago, without apparent cause, he commenced to have frequent urination at night, which was soon followed by frequency during the day; this symptom has gradually increased until his present condition is as follows:

Patient gets up from five to six times during the night and passes a few drops of cloudy ammoniacal urine; each act takes considerable time and is accompanied by intense vesical and rectal tenesmus, with severe burning pain in the prostate, urethra, and glans penis. During the day he has a desire to urinate about every thirty to sixty minutes, each act being similar to the ones at night, except more severe, the penis becoming congested and partially erect. Patient has been drawing his water with a small Coudé catheter, five to six times in the twenty-four hours, and washing the bladder morning and night with hot boracic acid solution. Of late catheterization has become very painful, and almost impossible at times, the only instrument that he can introduce being a small English gum catheter with stylet. Had retention one year ago, which was relieved by catheterization. Patient has become thin, anæmic, and very nervous from the continuous suffering. The straining has caused several hemorrhoidal masses to protrude. The urine is cloudy, alkaline in reaction, and ammoniacal; specific gravity, 1025; no sugar, casts, or albumin. Pus, $\frac{1}{10}$ by volume. About forty ounces are passed and drawn by catheter in twenty-four hours. External genitals are normal. Patient has good erections, with marked sexual desire.

The Urethra.—A small coudé catheter passes with great difficulty, and draws four ounces of foul, residual urine at 9½ inches from the meatus; this measurement was made with great care to the middle of the eye of the catheter, the patient being in the upright position. Thompson's searcher cannot be passed to the bladder, on account of the posterior median hypertrophy, which is very marked. The bladder holds six ounces of fluid. There is a severe cystitis.

Rectal examination shows the prostate to be very hard, smooth, and tense, and fully twice its normal size. The apex and edges are very prominent, rounded, and firm. The tip of the index finger can just reach the base. Pressure on the gland causes pain and an intense desire to urinate. Combined rectal and urethral examination of the prostate show that the obstruction to urination is due principally to the enlargement of the posterior median portion of the gland, rather than to a general hypertrophy.

December 11, 1894.—Ether; double castration. Cords and vessels tied with gut. Testes and epididymes normal; by an oversight they were not examined for spermatozoa. Slight hydrocele on each side; wounds left open and packed with iodoform gauze. No shock following operation. During the first twenty-four hours after operation there was such severe spasm of the compressor muscle that a catheter could not be passed, and the patient had to be aspirated several times. There was also spasm of the anal sphincter.

December 16th, 5th day.—A small, soft-rubber catheter passed to the bladder; this has not been possible for many months. The desire to urinate comes now about every four hours, at which time he is catheterized, and the bladder washed with hot salt solution. Vesical tenesmus and pain are greatly diminished. The urine is clearer, and is losing its ammoniacal odor.

December 21st, 10th day.—Patient has been up for several days. An 18 French soft-rubber catheter passes quite readily. Examination of the prostate per rectum shows the gland to be much softer in consistence, and absolutely painless on pressure. The apex and edges are much less prominent.

December 28th, 17th day.—Patient's general condition is greatly improved. The prostate feels softer and somewhat smaller than at last note (seven days ago).

January 1, 1895, 21st day.—Patient is gaining flesh, and says that "he eats and sleeps better than he has for years." He passed to-day by the urethra, in a stream, freely and with very little tenesmus, the following amounts of urine: At 4 A.M., 2 drachms; 11.30 A.M., 2 drachms; 3.30 P.M., 2 drachms; 9.30 P.M., 2 drachms.

January 2d, 22d day.—At 4 A.M., passed by the urethra, 5 drachms; 7 A.M., passed by the urethra, 7 drachms; at 7.30 P.M., passed by the urethra, 1 ounce.

January 4th, 24th day.—Total amount of urine voided by the urethra in twenty-four hours was six ounces.

January 8th, 28th day.—Passed eleven ounces by

[1] Read before the Genito-urinary Section of the Academy of Medicine, April 9, 1895.

the urethra to-day, and about one ounce each time. Is catheterized every five to six hours. Patient says "It is a pleasure to urinate and pass his soft-rubber catheter."

January 11th, 31st day.—Twenty-seven ounces passed by the urethra to-day; the largest amount at any one time being three ounces. Has a desire to urinate about every one to two hours.

January 16th, 36th day.—Passed thirty-three ounces by the urethra, the largest amount at any one time being four ounces. The stream is improving in force and size.

February 11th, 62d day.—Patient says he is "absolutely free from all pain." The improvement in his general condition is really quite marvellous; is gaining flesh, has a fine rosy color, and works at his profession, as a dentist, for several hours every day; is passing about thirty-four ounces of urine in twenty-four hours, and from one to six ounces at each time. In the morning and at bed-time he passes a soft-rubber catheter and washes his bladder with hot boric-acid, or salt solution. Urinates during the day freely and painlessly every two to three hours, and at night goes from three to five hours. Has had no erections or sexual desire since the operation, nor has there been any congestion of the penis during urination for the last month.

Examination of the Prostate per Rectum.—The apex and right lower border of the gland are still a little enlarged, but soft and non-painful; the remainder of the gland feels perfectly normal. There is no decrease in the length of the urethra, but patient says that the "lump at the neck of the bladder (about seven inches down) is getting smaller, and that the catheter passes it much more easily;" this so-called "lump" being in reality the hypertrophied posterior median portion of the gland.

March 17th, 95th day.—Patient has gained fifteen pounds since the operation. The urine comes in a good, free stream, without pain, straining, or tenesmus; but still contains a variable amount of pus. He sleeps from five to six hours every night without urinating, and during the day goes about every three to three and three-quarter hours. Patient says that he can hold his water for half an hour or so after the desire comes on. Passes about fifty-three ounces of urine in twenty-four hours. The urethra measures $8\frac{1}{4}$ inches in length; before the operation it was $9\frac{1}{2}$ inches, thus showing a decrease of $\frac{3}{4}$ of an inch. Thompson's searcher enters the bladder with ease: this was impossible before operation. The amount of residual urine has been reduced from four to two ounces. The bladder now holds fifteen ounces; before operation six ounces was the limit. Rectal examination shows the prostate to be normal in size and consistence, and absolutely painless, even upon firm pressure.

April 9th, 118th day.—Four months (lacking two days) have now passed since the operation. The patient's condition is practically the same as at the last note, on March 17th, although he says that he has more control over his bladder, and that he is gaining in every respect. He passes a soft-rubber catheter every night, and washes his bladder with hot boric-acid solution. These irrigations are continued, as there is still some cystitis, although the urine has lost its ammoniacal odor, contains less pus, and has become acid in reaction.

I may here state that when I first saw this patient, in December, 1893, he then had cystitis and enlargement of the prostate, but only to a slight degree, as a Thompson's searcher entered the bladder with ease, and the enlargement into the rectum was not very marked. He was then put upon internal treatment, regular catheterization, and bladder irrigations: but in spite of this treatment the prostate gradually increased in size, and he came to me in December, 1894, asking for some kind of surgical relief. Castration was suggested, on account of the sexual symptoms, and readily accepted, as he feared any operation either on the bladder or prostate.

In reporting a single case of castration for hypertrophied prostate, I appreciate fully that it alone proves nothing, and I therefore make no claims whatever as to the curative value of the operation in all cases, nor do I endorse it as a routine treatment, but merely lay before you an accurate clinical report of the results obtained during the first four months. I do believe, however, that when hypertrophy of the prostate is associated with such sexual manifestations as frequent erections, congestion of the penis during urination, and strong and almost constant sexual desire (as is so often observed in old prostatics) that by castration we remove the source of irritation, and by so doing relieve the congestion of the prostate, and in that way cause a softening and diminution in the size of the gland, which is naturally followed by an amelioration of the prostatic symptoms.

THREE EXPERIMENTS ON DOGS TO DETERMINE THE DURATION OF DIPHTHERIA ANTITOXIN IMMUNITY.

By A. P. OHLMACHER, M.D.,

DIRECTOR OF THE BACTERIOLOGICAL LABORATORY, MEDICAL DEPARTMENT, UNIVERSITY OF WOOSTER, CLEVELAND, O.

NEXT to the question of the therapeutic value of the new diphtheria remedy, its availability as an immunizing agent in human beings is of greatest importance. While we have enough clinical evidence now at hand to demonstrate the fact that an injection of the antitoxin confers a temporary immunity against diphtheria in the human subject, an insufficient amount of data are available to decide the question of the duration of this artificial immunity. The solution of the problem by direct experimental methods in man is naturally impossible, and we must therefore be content to accept the results of experiments on the higher mammals until a sufficient amount of clinical statistics shall have been accumulated. The general impression among specialists in this field of bacteriology is that the diphtheria-immunity induced by the antitoxin is of very short duration—the time being usually estimated at one or two weeks.

The experiments which I have here to record were made not only to determine the duration of antitoxin-immunity in dogs; but also to ascertain whether, in an artificial and temporary antitoxin-immunity, it would not be possible to stimulate the production of antitoxin in the blood of the dog by following the diphtheria

antitoxin with large doses of the diphtheria toxins. The success of such an experiment would pave the way for the rapid and cheapened production of the diphtheria remedy. While my hopes in this direction have been defeated, the negative results are still full of valuable suggestions.

Experiment 1.—A control experiment to determine the effects of the diphtheria toxins on the dog. A healthy male Newfoundland dog, weighing 35 pounds, was given an injection of 25 c.c. of the undiluted toxins.[1] Fifteen minutes after this dose, the dog's temperature rose to 102.5° F., and it was less lively than before the injection. Fifteen hours after the injection the dog was very sick, and would only rise to his feet after considerable urging. His temperature at this time was 101° F. He stood with feeble uncertainty, and when attempting to walk, fell on his side. These symptoms of weakness or partial paralysis, especially marked in the hind legs, became more pronounced until, eighteen hours after the injection, the animal lay helpless on its side. A marked increase in the frequency of urination was noticed during the last six hours of the dog's life; and later vomiting set in, followed by frequent, and ultimately bloody stools. Death occurred twenty-two hours after the injection of the diphtheria poison.

At the autopsy, made an hour after death, hemorrhagic foci were noticed in the omentum, pancreas, spleen, lungs, and especially in the mesenteric glands. The intestines were everywhere greatly injected, and a pronounced congestion was observed in the liver and other visceral organs. A marked œdema, and minute hemorrhages were present in the subcutaneous tissue around the injection-site. Pieces of the various tissues were fixed in Hermann's fluid for future microscopic study.

This experiment shows that these particular diphtheria toxins were exceedingly virulent, killing a large, healthy dog with symptoms of the most profound toxæmia in twenty-two hours, in a dose of 25 c.c.

Experiment 2.—To a healthy male Newfoundland dog, weighing sixty pounds, 25 c.c. of antitoxin[2] were administered hypodermically March 1, 1895. The animal showed no effect from this injection, and on March 9th, 40 c.c. of the toxins were injected. The next day the dog was perfectly well to all appearances. Forty hours after the injection the animal died quite suddenly, with none of the severe symptoms like vomiting, purging, and frequent urination preceding its death, as was the case in Experiment 1.

Evidently the antitoxin conferred a partial immunity of eight days' duration on this dog, since he tolerated for forty hours a two-fold dose of toxins which killed a control animal of half his weight in twenty-two hours.

Experiment 3.—A lively female dog, of the water-spaniel breed, weighing twenty-three pounds, was used in this experiment. On March 13th 10 c.c. of the diphtheria antitoxin were injected over the left shoulder; and twenty hours after the injection, 20 c.c. of the toxin were administered. The animal showed no local or general reaction to this dose of diphtheria poison, and two days following, 100 c.c. of blood were taken from its jugular vein. The serum obtained from this blood was tested for its immunizing power as detailed below.

Four days after the first injection of toxins another dose of 25 c.c. was given. The morning following this injection the dog vomited once, and for two days she showed considerable lameness in the left shoulder and leg. Six days later, or eleven days after the use of the antitoxin, 30 c.c. of toxins were administered. This injection was followed by a marked local swelling, which gave place to an indurated and partially necrotic area of skin extending around the injection puncture for 6 to 8 ctm. For two days the dog remained in her box, and seemed unable to move on account of a great lameness of the left leg. This disability persisted for two or three days, when the animal gradually recovered, though some lameness of the left shoulder was apparent at the end of a week. During the first two days following this injection the dog's appetite was capricious and it vomited once or twice. Four days after the injection of these last toxins the dog was again bled for 50 c.c. of blood, from which the serum was obtained.

From this experiment it appears that at the end of twenty hours after the injection of the diphtheria antitoxin a perfect immunity against a large dose of these very powerful toxins was present. At the end of four days the immunity was partially lost, and at the end of eleven days the protection had so far subsided that the dog's life was seriously threatened by a dose of 30 c.c. of the toxins. Still, in virtue of the antitoxin immunity, the animal was enabled to withstand, without fatal consequences, 75 c.c. of this deadly poison.

No further experiment has been made on this dog, which has now regained its health, as I am convined that another dose of toxins would kill it.

In order to answer the question concerning the immunizing value of the blood-serum of an animal artificially immunized by diphtheria antitoxin, and then subjected to a large dose of diphtheria toxins, the following experiments were made.

Experiment 4.—The serum obtained at the first bleeding of the dog in Experiment 3 was employed. A large female guinea-pig, weighing 540 grammes, was given an hypodermic injection of 0.25 c.c. of the dog's serum. At the same time a control pig, weighing 520 grammes, was injected with 0.1 c.c. of the same toxins employed in the three above-described experiments. The control animal died between the twenty-fourth and thirty-sixth hour after the injection. Twenty hours after the injection of the dog's serum, 0.5 c.c. of the toxins were given to the first pig. This dose represented five times the fatal quantity of the toxins, and the pig died between the thirty-sixth and fortieth hour after getting it. The dog's serum from the first bleeding apparently possessed little, if any, immunizing value.

Experiment 5.—A 600-gramme female guinea-pig was given 1.00 c.c. of the diphtheria toxins, mixed with 0.5 c.c. of the serum of the dog obtained at the second bleeding. The guinea-pig died twenty-eight hours after the injection, thus proving that the serum from the second bleeding possessed no appreciable neutralizing effect on the toxins when mixed in a proportion of 10 toxins (ten times the fatal dose) to 5 serum.

It would seem fair to conclude from these experiments: 1. That the immunity conferred by an injection of the diphtheria antitoxin is powerfully operative at the end of twenty hours. 2. That this immunity gradually diminishes in the week following the injection. 3. That at the end of eight days the immunity is very much diminished. 4. That the blood-serum of a dog rendered immune against the diphtheria toxin by an injection of diphtheria antitoxin, does not attain pronounced antidotal properties, even though the dog successfully withstands large doses of the toxin.

In the present insecurity of our knowledge concerning the exact nature of the diphtheria antitoxin, and of the seat and method of its production in the animal economy, it is hazardous to attempt the explanation of

[1] These toxins were of the same lot as those injected into our diphtheria-immune horse (see Medical News, March 16, 1895), and were of such a potency that 0.1 c.c. invariably killed a 500-gramme guinea-pig in thirty hours. The horse tolerates, without reaction, a subcutaneous injection of 250 c.c. of these toxins. In proportion to the weight of the animals, it will be seen that a dose of 25 c.c., in the dog is considerably more than the maximum dose employed in the horse.

[2] This antitoxin was obtained from our diphtheria-immune horse at the first large bleeding. The serum was the last abstracted from the blood, and was discarded for clinical purposes on account of its red color. Experiments on guinea-pigs have shown the antitoxin of this bleeding to possess an immunizing value of at least 1 to 60,000, according to the French notation.

many of the curious phenomena witnessed in immunity against this particular disease. As a provisional explanation of certain features of the experiments just detailed, I have assumed that the immunity produced by an injection of diphtheria antitoxin is successful only on account of the presence of the artificially introduced antitoxin *per se;* and that the immunity subsides as the antitoxin is secreted. That is to say that in itself, the antitoxin does not stimulate a further production of an effective antidote in the animal in which it is injected. Moreover, the antitoxin seems to *neutralize*, more or less perfectly, the subsequently administered diphtheria toxins, without calling into play any active defensive function on the part of the animal itself. As a result, no marked production of an antidote occurs in the animal's body, even though it tolerates enormous doses of diphtheritic poisons, as would certainly be the case were the toxins administered alone, in gradually increasing doses, as is now done in the preparation of the new diphtheria remedy.

EPIDEMIC OF TYPHOID FEVER.[1]

Eighty-one Cases—Three Deaths—Treatment.

By C. A. RAY, M.D.,

WINIFREDE, W. VA.

Winifrede is a mining village of about sixteen hundred inhabitants, situated on Field's Creek, a small tributary of the Kanawha River, fourteen miles east of Charlestown. The dwellings, about three hundred and fifty in number, are located along the valley for a distance of four miles. The water-supply is obtained from springs and surface wells. Notwithstanding the efforts upon the part of the Winifrede Coal Company to have our town a healthy locality, the sanitary conditions and hygienic surroundings are far from perfect.

At the extreme upper end of the village is a cluster of houses, six in number, the water-supply being from a small spring. About February 1, 1894, a family moved from up the Kanawha into one of these houses, immediately above and about one hundred feet from this spring. Four or five days afterward, one of this family, a young man, aged eighteen, was stricken with typhoid fever, which ran its usual course of four or five weeks. Regardless of the protestations of the family physician (I was not the attending physician in this family), the slops, alvine discharges, etc., were thrown out without disinfection and ran directly into the spring. During the third week of this young man's illness four others of the same family were stricken with the malady, and within ten days there were seventeen cases in the above-mentioned six houses. About three hundred yards below this spring is a dam, built for the purpose of piping the water to a tank three hundred yards farther down the branch, where the locomotives are supplied. A family using water from this tank had six cases, and, of the trainmen who drank water from the engine tanks, three were attacked at the same time, and in the first week of the first seventeen cases mentioned. At Winifrede Junction, six and a half miles from this spring, several families, rather than carry water up the river bank, drew it from the engine tanks, and the result was that five cases developed in as many families, making in all, at one and the same time, thirty-one cases. From here the malady spread until the total number of cases far exceeded one hundred, and continued till the latter part of November, 1894, concluding with my friend and colleague, Dr. A. M. Spangler, who, after a siege of six weeks and one severe relapse, made, I am glad to say, a good and perfect recovery. I was not able to make a chemical or microscopical examination of the water, but the preceding facts and the typical type of the large majority of cases, I think, make it conclusive that the disease was typhoid fever, and the water the source of infection.

I have here a few statistics relative to the 81 cases herein reported:

Number of males	49
Number of females	32
Number of males over twenty-five years of age	18
Number of males from fifteen to twenty-five years of age	13
Number of males under fifteen years of age	18
Number of females over twenty-five years of age	9
Number of females from fifteen to twenty-five years of age	9
Number of females under fifteen years of age	14
Total	81

Dr. Spangler has kindly handed me the following statement:

Number of males	42
Number of females	31
Number of males over twenty-five years of age	15
Number of males between fifteen and twenty-five years of age	22
Number of males under fifteen years of age	5
Number of females over twenty-five years of age	14
Number of females between fifteen and twenty-five years of age	8
Number of females under fifteen years of age	9
Total	73

Making a total of all cases during the epidemic of 154.

Number of cases of relapse, 9. Number of cases of recurrence of fever, 11, followed in 2 cases by relapse, coming on in 1 case after temperature had been normal five days, and in the other eight days.

Complications and sequelæ worthy of notice: Pneumonia in 2 cases; intestinal hemorrhage in 2 cases; pleurisy in 2 cases; acute mania in 1 case; cerebral meningitis in 1 case; facial erysipelas in 1 case; bradycardia, or slow pulse, in 4 cases, in 1 case reaching as low as 32 per minute, when the temperature would be 103½° F., and remaining below 45 two weeks after temperature had reached normal.

Constipation in 51 cases after the second week, due, I think, to the almost exclusive milk diet, a practice which I shall hereafter avoid in the treatment of typhoid fever. Average duration, twenty-six days, the most protracted case being seventy-eight days, and the shortest thirteen days. Number of deaths, 3. Per cent. of mortality, 3¾.

Cases of Particular Interest.—Case I.—David L——, aged forty, married, was taken ill May 13th. My first visit in the afternoon of the 15th; temperature, 101½° F.; pulse, 90; diarrhœa for three or four days; tongue dry; nose bled the day before. Temperature gradually arose till, on the 18th, it reached 103⅘° F.—this being the highest evening temperature for ten days—when it began to decline, and reached the normal point six days later, or June 4th, all other symptoms improving accordingly. On June 6th the evening temperature was 102½° F., and on the 7th reached 106⅕° F., and continued so, when not reduced by antipyretics, for sixteen days, when it began to decline, and ten days later reached normal, where it remained for eight days, gradually rising again, one degree each day, till the maximum, 103° F., was reached, and again gradually declining, the P.M. temperature being normal for the first time twenty days after the beginning.

Case II.—Joe H——, aged fourteen. Taken ill April 1st. A repetition of the preceding case is the history of this one. The highest temperature of the primary attack, 102½° F., of the recurrence, 106⅕° F., and of the relapse, 102⅘° F. The duration in the former being seventy-eight days, and in this one sixty-seven days. The most perplexing point about these two cases is why a relapse and recurrence should occur, when they were (with one or two exceptions) the only cases under perfect hygienic surroundings and the care of a trained nurse. Self-reinfection is the only solution.

[1] Read before the Charleston Medical Society, March 24, 1895.

Case III.—Sam C——, aged twenty-four, single. Taken ill on April 12th; gradual rise of temperature to 103½° F. on the 19th; began to decline on the 25th, and was normal on May 1st, or the twenty-first day. I informed him that he could sit up on the next day. I called next afternoon and found his temperature 104° F.; abdomen greatly distended; pulse, 108; marked delirium and diarrhœa. Was told by the attendant that a friend had left three or four oranges on the table the night before, and that they had disappeared. Ordered two drachms of castor-oil and thirty drops of spirits of turpentine. Next morning found him much better; temperature, 102° F.; pulse, 100. Left three powders of acetanilid, four grains each, with instructions to give one if the temperature reached 103½° F., and asked a nurse who was attending a case next door to take his temperature, which he did, and gave him one powder at 10.30 P.M., his temperature going to 103° F. The next morning his grandmother, thinking he had a "tremendous fever," gave him another powder. Ten minutes later his temperature was 99° F.; pulse, 100. The same afternoon his temperature was 94° F.; pulse, 145; and, despite the hypodermic use of strychnia, strophanthus, brandy, sulphuric ether, etc., the young man died three days later from heart failure.

Case IV.—Mrs. J. M——, aged twenty-five. Taken ill July 25th. Highest temperature, on tenth day, 103½° F. Severe diarrhœa, resisting all treatment; four hemorrhages during afternoon and night of twelfth day. Rallied, and diarrhœa ceased after hemorrhages, and temperature gradually declined to normal on the twenty-second day, remaining normal for three days, when a child carried her some boiled cabbage and potatoes, of which she ate, and fever and diarrhœa returned, temperature not going higher, however, than 102½° F., and gradually declining to normal after four weeks, at which time she was very much emaciated: pulse, 60; mentally dull; bowels constipated; pupils irregular and responding to light very slowly; severe headache; abdomen contracted. The above symptoms gradually increasing until there was retention of urine, with corneal ulceration, and she died, comatose, October 17th.

Case V.—Celia M——, aged twenty-two, the third fatal case, was a poor girl living back some distance in the country, whom I saw but three times, and who died from hemorrhage and heart failure on the tenth day of her illness.

Case VI.—John D——, aged nine. Taken ill August 8th. Saw him two days later, when temperature was 102⅘° F.; pulse, 120; severe diarrhœa; nose bleeding; abdomen distended and tender. On the seventh day his temperature went down to 96½° F., and remained subnormal for five weeks. At the same time all other typhoid symptoms were well marked, such as delirium, diarrhœa, epistaxis, pulse, dry tongue, eruption, etc. The lamented Dr. A. E. Aultz saw this patient and concurred in my diagnosis, pronouncing it one of the "medical wonders."

Case VII.—Mrs. J. E——, aged twenty-one, married. Taken ill on June 12th; marked typhoid symptoms: temperature going as high as 105½° F.; pulse, 150; delirium active; diarrhœa severe, stools being involuntary; considerable epistaxis, but no intestinal hemorrhage; temperature began to decline and consciousness returned during the sixth week, and at end of seventh temperature reached the normal point. About this time she became very cross, and expressed frequent and great desire for food. Being limited, of course, as to quantity and quality, she soon developed a typical case of acute mania, lasting eight weeks, her principal delusion being the blissfulness of starvation in a land of plenty.

There were several interesting cases, of which I shall not worry you with details: Two with pleurisy, one with facial erysipelas, recurring the second time and extending over one-half the surface of the body, and three cases in which the eruption was so well marked that it extended over the entire surface, resembling very much the eruption of measles.

Treatment.—I shall not go into details of treatment farther than to say that the initial dose of calomel was given in nearly every case, with happy results, the temperature going down for forty-eight hours thereafter. Hydrochloric acid with pepsin preparations in all cases. Salol, enteric creosote pills, and quinine in solution, in cases where intestinal antiseptics were indicated. All the ice-water they wished to drink. Enema of warm water for constipation always. No laxatives given except in cases where diarrhœa did not respond to ordinary remedies and the presence of foreign matter was suspected. Brandy, strophanthus, and strychnia when the heart began to show signs of failure. Temperature reduced by baths and ice-water enema in most cases. Acetanilid, phenacetin, and antipyrin in some of the most robust patients. Diet almost exclusively milk, either peptonized or sterilized.

Conclusion.—There is not a disease in the annals of medical science so universal and so long known to the profession in which our knowledge is so deficient. We do know that typhoid fever is a contagious, infectious, self-limited disease, running a course of two to ten weeks, and while you scarcely see it mentioned in text-books, varies greater in type and severity than either measles or scarlet fever. In no other disease is the attending physician so often confronted with that most perplexing question in the practice of medicine—the relation of cause and effect. Too often are we implored by friends and relations to give something for unimportant symptoms. Too often do the anxious friends and relations show signs of dissatisfaction with the progress of our case, and we resort to measures of relief, which, in our own conscience, we deprecate. Not until the laity is educated up to these points will we be able to keep our meddlesome hands off, as we are now prone to do in the treatment of pneumonia and treat typhoid fever successfully. When I began practice at my present location several years ago, I battled for dear life with every case of typhoid fever, and the per cent. of mortality in my first two hundred cases was far in excess of three and three-quarters. In the present epidemic I treated the patient, not the disease, and I am satisfied with, if not proud of, the results. I do not mean to say that we can lay aside all therapeutic agents, but I do say the tendency of to-day is to give too much medicine, and the physician who follows a routine will fail utterly. Antipyretics we must use, and of these I have great faith in baths according to the Brandt method, but you cannot use them in all cases, for I have seen patients with typhoid fever whom you could not bathe with any more satisfaction or relief than you could a case of hydrophobia. Aconite, veratrum, digitalis, and nitro-glycerine I never use. Of the coal-tar extracts I prefer phenacetin, and would use that with caution. Of acetanilid and antifebrin, I shall never give another dose in typhoid fever, for I feel this evening that had I, in the case of the young man who died, thrown the powders of acetanilid into the fire and trusted to good nature and a little water, instead of giving them to the old grandmother, I might have headed this paper, "Eighty-one cases of Typhoid Fever, with Two Deaths," instead of three.

The Influenza Epidemic in London has been most severe. During two weeks in March there were 769 deaths, exceeding the mortality for the entire year 1894. The disease has prevailed also throughout the British Isles. In Scotland the death-rate for February of this year was forty-five per cent. higher than that of any previous February since records have been kept. This increase was almost entirely in deaths from influenza and pulmonary affections resulting from it.

SYMPHYSEOTOMY; A CASE OCCURRING IN PRIVATE PRACTICE.[1]

By JOSEPH M. RECTOR, M.D.,

JERSEY CITY, N. J.

The early accoucheur, when confronted with an abnormal childbirth, due either to deformity in the diameters of the female pelvis, or excessive enlargement of the fœtal head, had recourse but to one means of saving the unfortunate woman's life, that of Cæsarean section, and while this operation was offered as a means of safety to the patient, it was of little consolation because of the high percentage of mortality.

In 1644 Jean de la Courvée proposed division of the symphysis pubis as a remedy for the difficulty, and performed the operation of symphyseotomy; but little success attended his efforts, and with him the operation fell into disuse.

Sigault, of Paris, revived the operation in 1777, but it was left to Morisani, of Naples, in 1866, to again bring symphyseotomy before the notice of the medical world, and to him is credited the honor of placing this operation upon a scientific footing. The many surgeons of Italy at once followed his example, and from the year 1777 to 1858, eighty-six cases were recorded in Italy alone, while for the next twenty years following, seventy-six cases were reported at Naples.

In France the operation did not seem to meet approval until within the last two or three years, when favorable reports were received from Tarnier, Pinard, and Charpentier. The Germans (Freund, Zweifel, Leopold), were the next to advocate symphyseotomy, while in the United States, Dr. Jewett, of Brooklyn, gives to us the first recorded case, in September, 1892.

The French, under the guidance of Sigault, and the Germans, under Freund and Zweifel, have practised the so-called "open method," viz., an incision is made over the symphysis pubis varying in length according to the operator's selection, a stiff catheter is passed into the urethra, and this is held to one side. The finger is passed behind the symphysis on this as a guide, and with a probe-pointed bistoury an incision is made in the cartilage from above downward, and from within outward. The Italians under Morisani and Spinelli prefer the "subcutaneous method," viz., an incision is made in the median line from 3 to 3½ ctm. in length, and terminates 1 or 2 ctm. above the symphysis. The musculi pyramidales are next divided by transverse incisions. The finger is passed downward behind the symphysis and under its inferior border, on this as a guide, Galbaiti's falcetta is carried under the symphysis pubis and the cartilage is divided from below upward, and from within outward.

After the operation it seems to be a matter of choice and preference with the accoucheur whether he shall deliver at once or desist from further interference, allowing nature to complete the delivery. The condition of the mother or the changes in the fœtal heart sounds are his best guides. Zweifel recommends non-interference for twelve hours; Morisani uses forceps in about one-fourth of all vertex cases; Garrigues generally delivers the woman at once.

After the delivery, Pinard places his patient in a bed especially constructed for that purpose. Zweifel sutures the bones together. Garrigues places strips of adhesive plaster around the pelvis and over the trochanters.

On August 21, 1894, at two o'clock in the morning, I was called to the bedside of Mrs. O——, in the tenement district of our city, and found her to be in labor. Upon inquiry I learned that her uterine contractions had begun the day before, they had continued at fifteen-minute intervals, until, at half past one o'clock on the next morning the membranes had ruptured. Upon examining my patient I found the abdomen to be enormously distended, so large that to my mind it suggested the possibility of twin pregnancy, or dropsy of the amniotic fluid. The fœtal heart sounds could be distinctly heard in the right iliac region, and the child was presenting by the vertex, the occiput being to the right and posterior. The vaginal examination proved to me the probability of further trouble in that the internal conjugate diameter was markedly contracted, while the transverse diameter at the brim was somewhat elongated, and the sacral promontory projected well forward into the cavity of the pelvis.

Mrs. O—— is twenty-seven years of age. There is no history of continued sickness in childhood. She has been married three years. Dysmenorrhœa and metrorrhagia are the only pathological conditions of the uterus that have been noticed. In February, 1892, she had one miscarriage. In March, 1893, she gave birth to a small child which lived but two weeks, and upon asking the physician in attendance I learned that the delivery had been an instrumental one.

After the rupture of the membranes the uterine contractions became frequent and stormy, repeated vaginal examinations gave no signs that the vertex was advancing. At five o'clock I applied high forceps and succeeded in bringing down the head but little; after frequent attempts I found the forceps would lose their grip upon the vertex. At six o'clock I called to my assistance Dr. Gray, forceps were again applied, with the same result. Craniotomy or cephalotripsy now seemed our only hope, and with that end in view Dr. Dickinson was summoned. Again high forceps were applied, this time the Tanier axis-traction forceps were used, but they slipped in like manner.

It was now eight o'clock in the morning; in spite of the repeated and prolonged use of chloroform our patient was in an excellent condition, while the fœtal heart sounds were as near distinct as before. Symphyseotomy was proposed, as it offered a means of safety to both mother and child. Our patient was removed at once to the hospital.

Dr. Gray began the operation at ten o'clock, Dr. Dickinson was associated with him, with myself as an assistant. The open method, as before described, was used, with the exception that the subpubic ligament alone remained intact. The division in the symphysis was made with an ordinary blunt-pointed curved bistoury, and great difficulty was experienced because the instrument was not of sufficient strength to withstand the force which it was found necessary to apply in order that the division might be accomplished. The operation would have been facilitated by the use of the Galbaiti falcetta, which could not be obtained without considerable delay and difficulty.

A gaping took place at the upper portion of the symphysis which was of sufficient space to allow the insertion of the index and middle fingers. High forceps were now applied and upon making traction the subpubic ligament was easily torn and with it a long rent occurred in the anterior vaginal wall. At this moment the separation between the pubic bones was about two inches. Traction was continued and a living child was born. A slight uterine hemorrhage followed the delivery and considerable oozing from the newly made wound.

The child, a male, weighing ten and one-half pounds, was in a condition of asphyxiation, and seeing its life at stake I at once resorted to the usual means for its resuscitation. The baby did not return to its normal condition as rapidly as it should have done, and I thought it best to examine him for injuries which he might have received, and I found a multiple fracture at the base of the occipital bone, which I judge must have happened during our efforts at extraction. The child lived six hours after its birth. Its length of body was 23 inches; biparietal circumference of head, 16½ inches; circumference of chest at armpit, 15 inches; weight, 10½ pounds.

Pressure inward was made over both trochanters of the patient, the wound was closed with four silkworm-

[1] Read before the Hudson County N. J., District Medical Society, December 4, 1894.

gut sutures, and a small piece of iodoform gauze served as drainage. The vagina was likewise tamponed with iodoform gauze. A tight muslin binder extending from the axilla to the middle of the thighs easily kept the divided pubic bones in close contact.

After the operation the patient was given five grains of ergotine hypodermically, also one-thirtieth of a grain of strychnine sulphate. The foot of the bed was elevated. During the day the patient was stimulated with brandy and digitalis, and given one-half drachm of ergot every four hours. The temperature averaged 100.9° F.; respiration, 24; pulse, 112. There was no vomiting; milk, lime-water, and broth served as nourishment.

August 22 (second day).—Average temperature, 99.1° F.; respiration, 25; pulse, 98.4.

August 24th (fourth day).—She had a rise of temperature reaching 102.8° F. Two stitches were removed and about a drachm of serum was present; the wound was irrigated and dressings re-applied; the temperature fell, and from this time on she made a good recovery.

September 13th (twenty-third day).—The patient was able to walk about supported under her shoulders. The wound had firmly healed, the pubic bones were in good apposition, the separation of the opposed surfaces was about one-quarter of an inch, the patient had a slight waddling gait, there was an extensive laceration of the cervix and perineum, with slight rectocele.

On September 15th (twenty-fifth day), the patient underwent a second operation for the relief of the lacerated cervix and perineum. Three weeks after this operation the patient left the hospital, she had entirely recovered from the effects of both operations, and was able to continue her daily labors with as much ease as before the primary operation.

In this case which I have brought to your notice, I desire to call attention to the excellent result that has been obtained as to the firmness of union in the divided symphysis, since no other precaution was taken to hold in apposition the cut surfaces of the pubic bones, otherwise than the tight muslin abdominal binder as ordinarily used for the lying-in woman, and again to mention the fact that there was no tendency to the separation of the joint, possibly owing to the firm action of the sacro-iliac ligaments.

Dr. Gray has suggested as a matter of practical importance in the technique of the operation, the desirability for the complete division of the pubic ligaments before attempting to deliver the patient; he is satisfied that the rent in the anterior vaginal wall was caused by the sudden separation of the joint and the consequent distention of the vagina, due to the snapping of the subpubic ligament under the strain of the descending head; had all the ligaments been divided at once the distention would have been gradual and no damage done to the anterior vaginal wall.

This case is brought to your notice to-night because of the frequent references made to symphyseotomy in our medical journals, and because I take it to be the first case of symphyseotomy that has been reported in New Jersey. I have not gone into the discussions pro and con, nor have I stated the advantages or the disadvantages of the operation, I merely ask your attention to this existing condition, which each one of us is liable to meet at almost any moment in his daily practice, and desire you to remember that in the operation of symphyseotomy we have a possible means of safety and protection to the life of both mother and child.

English Dentists.—There are 4,874 registered dentists in Great Britain, of whom 3,479 practise with no special qualification, but on the strength of their own declaration that they were engaged in the practice of dentistry before the passing of the recent act regulating the profession.

RUPTURE OF THE LEFT VENTRICLE—STUDY OF A CASE.

By HERBERT UPHAM WILLIAMS, M.D.,

BUFFALO, N. Y.

Of this case only the following facts relating to the history and post-mortem were obtainable. The patient was a lady about fifty years of age, who, for some years, had had attacks of epigastric pain which may have been anginoid in character. Although spare and not very vigorous, her general health was pretty good. A few days before her death she had one of the painful seizures mentioned, which subsided after taking soda, returning after a while, this time being subdued by chloranodyne, only to return again, the last time with such severity as to require morphine hypodermically. The patient was kept in bed. Morphine was given only once. About the third morning from the beginning the pain became extremely severe, the patient sat up in bed.

The autopsy was not complete, but as far as pursued revealed no striking abnormality outside of the pericardial cavity. The latter contained several ounces of clotted blood. The heart was of moderate size, subpericardial fat abundant, muscle pale, thin, and flabby. The source of the blood was found in a rent in the anterior wall of the left ventricle. An opportunity to examine it I owe to the courtesy of Dr. DeLancey Rochester.

The point of rupture was located 25 mm. to the left of the right margin of the left ventricle, about midway between its apex and base. The external opening was 9 mm. in length, the internal, 16 mm.; both were slit-like and somewhat irregular, passing obliquely from left to right and above downward. The wall of the ventricle at its thickest was 12 mm., of which 4 mm. were fat; at the apex it was 6 mm., nearly all fat. Near the point of rupture, the wall was decidedly more attenuated than at a short distance removed from it. The right ventricle measured 6 mm. in thickness, nearly all fat. An irregular area, including the point of rupture, extending above it on the left ventricle, passing a short distance on the right ventricle, was elevated, dark, and hard, evidently infiltrated with blood, as was proven by histological examination. This region measured 62 × 37 mm.

The valves of the heart appeared normal except for slight thickening of the posterior segment of the mitral. The aorta showed a few small patches of atheroma in the fatty condition; circumference of aorta, 68 mm. The left coronary artery was followed from its origin down the anterior surface of the ventricle. About 25 mm. from the base of the heart and the origin of its transverse branch it bifurcated, the seat of rupture being included between the bifurcating branches. Of the bifurcating branches the right exhibited several small calcareous plates, and one large plate 12 mm. in length. In contact with this plate lay a soft, reddish-white thrombus of the same length, completely filling the lumen of the artery.

A section made of the left coronary artery near its origin showed a part of the wall swollen and containing abundant nuclei, and in the middle of the patch an irregular excavation starting from the inner side, passing half way through the media. Dissection of the right coronary artery showed no such atheromatous condition as was found in the left.

Section of a portion of the ragged heart-muscle about the point of rupture showed an abundant infiltration of round cells between the columns of muscle-cells, or between the individual cells. The cross striæ were often indistinct and on some muscle-cells not visible at all. Many cells were slightly granular. A few irregular, dark, granular masses appeared to have resulted from the disintegration of muscle-cells. Most of the muscle-cells appeared very long and slender. Nuclei were discernible only over part of them.

A section made through the wall of the left ventricle,

but behind, and removed from the seat of rupture, showed the muscle-fibres to be of the normal average diameter. Individual cells were enlarged, others smaller than normal. The cross striations were distinct, longitudinal fibrillation well marked. An abundance of large, yellowish-brown granules filled the central parts of the muscle-cells about the nuclei, and extended some distance toward the poles of the cells. Many cells were observed having two nuclei; the space between the two nuclei being filled with pigment granules. Numerous elongated inter-muscular nuclei were seen. The amount of inter-muscular connective tissue was not unusual. The sub-pericardial fat was abundant, passing also into the muscular layers to a moderate extent along the course of the vessels. A few inconspicuous white flecks on the papillary muscles were seen, which proved to be due to fibrous connective tissue.

The progress of events in this heart is not hard to trace. There was atheroma of the left coronary artery, which was most marked in its right branch. A region of the wall of the left ventricle corresponding to the distribution of this vessel became on that account thin and atrophic. A thrombosis of the vessel occurred as a result of the roughened calcareous plate formed in the atheroma. There ensued in consequence of the thrombosis, anæmia, and in consequence of the anæmia, necrosis, in part of the thinned area mentioned. The blood in the ventricle under pressure dissected its way slowly through the necrotic and softened muscle. There was time for cell infiltration to occur. The blood dissected its way some distance in various directions from the ruptured point, infiltrating the muscle and even the sub-pericardial fat. It seems to have been some days making its way through the wall of the heart, finally bursting it, nearly opposite the internal point of rupture. The separation and laceration of the muscle-fibres was accompanied by severe pain.

The history of previous similar but less painful attacks is suggestive when we recall the presence of atheroma of the coronary. There seems to have been no interstitial myocarditis of importance; nor does the fatty infiltration of the heart that was present seem to have affected the progress of events. The specimen had been preserved a long time in alcohol when it reached my hands, which made the search for fatty metamorphosis unreliable; however, none was observed.

Laboratory of Pathology, University of Buffalo.

A French Schedule of Fees.—There is nothing like living under a socialistic and paternal government. In one of the departments of France, that of Yonne, the authorities have prescribed the following schedule of fees: "Extraction of a tooth, 1 franc; bleeding, 2 francs; opening an abscess, 1 franc; applying the speculum, 2 francs; hypodermic injection, including supply of solution, 1 franc; reduction of hernia by taxis, 2 francs; puncture of a hydrocele, 3 francs; operation for phimosis, 5 francs; reduction of phimosis, 3 francs; fracture of the lower jaw, 5 francs; fracture of the clavicle, 3 francs; of the arm, 5 francs; of the forearm, 5 francs; of the leg, 5 francs; of the fibula, 5 francs; of the femur, 5 francs; dislocation of the elbow, 5 francs; of the shoulder, 5 francs; of the ankle, 5 francs; of the knee, 5 francs; of the femur, 10 francs; tracheotomy, 30 francs; administration of chloroform, including supply of the chloroform, 5 francs; turning, 10 francs; removal of placenta, 10 francs; applying the actual cautery, 2 francs; amputation of a limb in a case of extreme urgency, 30 francs; application of the forceps, 10 francs."

We commend this schedule to some of our Kansas statesmen. Six dollars for amputating a limb seems very reasonable; and twenty cents for a hypodermic injection including the medicine would also make medication of this kind most popular.

Clinical Department.

PLACENTA RETAINED IN UTERO ONE YEAR —IMPREGNATION—FŒTAL SAC OVER OS INTERNUM—HEMORRHAGE AS IN PLACENTA PRÆVIA—OUTERBRIDGE'S IRRIGATING CERVICAL DIVULSOR.[1]

By A. ERNEST GALLANT, M.D.,

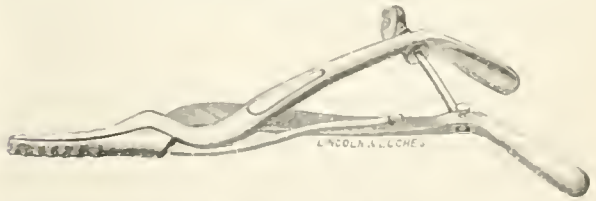
GYNECOLOGIST TO THE NORTHERN DISPENSARY; ASSISTANT GYNECOLOGIST ROOSEVELT HOSPITAL, OUT-PATIENT DEPARTMENT, ETC.

My purpose in presenting the following history is threefold, viz.: 1. To relate a case of which comparatively few are on record. 2. How, in similar cases, can the presence of a fœtal sac be determined? 3. To present a new irrigating cervical divulsor devised by Dr. Paul Outerbridge, of this city.

L. T——, German, housewife, mother of two children, youngest three and a half years of age, was referred to the writer at the Northern Dispensary, on March 30, 1894. Her statements were as follows: She had been flowing for the past four or five weeks. Not much, but a little all the time. Miscarried at the fifth or sixth month in March, 1893. She flowed severely for two weeks after, then stopped, and menstruation recurred, at regular intervals of four weeks—three days; small quantity, natural color, up to and including January 18 to 21, 1894. Did not menstruate in February, but has had a constant "show" for the past four or five weeks.

Digital examination showed the cervix two inches in diameter, lacerated bilaterally, rather congested. Uterus forward, fundus extending two and one-half inches above the symphysis; body large, flabby; walls easily brought together, and tender on pressure. Sound entered easily; cavity five and one-quarter inches deep, roomy; fungosities and blood on the sound when withdrawn, followed by a little bloody serum. Breasts show no recent changes. Diagnosis: Subinvolution from retained placenta.

Curettage advised, and arranged to do so on the next day, but at that time found that, after an hour's "cramps" the patient had expelled a sac containing fœtus and fluid complete. Not feeling satisfied that this constituted all the contents of the uterus, on making a digital examination found the cervix filled with a considerable mass of degenerated placental tissue. In order to clean out the uterus the cervix was divulsed and thoroughly scraped, first with a dull, and then a sharp, curette; a large amount of loosely adherent placental tissue being brought away. Hot water, introtroduced through Outerbridge's irrigating divulsor



Outerbridge's Irrigating Cervical Divulsor.

(here presented), failing to excite contraction of the very flabby uterine wall, tincture of iodine sufficient to give a sherry color to the hot water was run into the cavity and at once caused a diminution in size to three and a half inches. Hot water was then used to wash out the tinctured solution. Seven and a half yards of one-inch wide, plain sterilized gauze was packed in the uterus, and the patient walked to bed. She suffered from cramps during the night. Forty-eight hours after the partially extruded gauze was removed, that in the uterine cavity being perfectly sweet. Hot water vaginal douches *ter die*. On the fourth day the uterus

[1] Read before the New York Academy of Medicine, Section on Obstetrics and Gynecology, February 28, 1895.

was firmly contracted—in good position. From the first the patient got out of bed to urinate and defecate.

All instruments, gauze, etc., were sterilized at the office, wrapped in a clean towel, and submerged in boiling water at the house. The genitals and vaginal canal were thoroughly washed with tincture of green soap, and irrigated with plain hot water previous to dilatation of the cervical canal. No antiseptics were used in any part of the operation. The surroundings were of the worst possible character—a basement in West Houston Street—and the bed linen extremely dirty, yet no symptom of infection appeared, due, as the writer believes, to the use of strictly clean instruments, etc.

The fœtus and sac were mounted by Dr. Henry Power, at the Histologic Laboratory of the College of Physicians and Surgeons, and the fœtus pronounced to be ten weeks old. Chorionic villi are present over the whole uterine surface, except at that portion which lay directly over the os internum, where the villi had atrophied, this being the cause and seat from which the hemorrhage proceeded. The placenta was not yet defined.

The congested condition of the cervix, ten weeks' amenorrhœa, and character of the flow pointed to the presence of a fœtal sac over or near the os internum. On the other hand, the history of miscarriage, the large size and flabby condition of the uterus, showing chronic subinvolution; the large, soft, wide, open os, with the extreme probability of placenta prævia, induced me to pass the sound, which entered with such ease as to allay my suspicions of the presence of a fœtal sac and to advise curettage. The sequel, to my mind, justifies the course pursued.

Outerbridge's irrigating cervical divulsor may be described as a combination of Wathen's cervical divulsor with the irrigating tube of Dudley's divulsing irrigator inserted into the right blade, and offers the following useful features, viz.:

1. That it cleans out the uterine cavity in a more thorough and efficient way than any double-current catheter can do.

2. All that is needed is an ordinary douche bag, the rubber-tubing of which easily fits over the end of the irrigating tube.

3. That with the blades held apart by the screw on the handles, the cervix cannot close down and obstruct the outflow.

4. The stream of fluid readily strikes the fundus, while, if it is deemed advantageous so to do, the blades can be alternately opened and closed.

5. The very fact that the cervix is put on the stretch, while the interior is irritated by the injection of boiled water, or other fluid, tends to act as a mechanical irritant and causes the body to contract.

6. No extra double-current catheter is needed, and that it cannot get out of order, be lost, or left behind, when most needed.

7. That the combination does not lessen the usefulness of Walthen's divulsor for ordinary purposes; and,

8. Being constructed entirely of forged steel it is much stronger than the ordinary instrument, and easily rendered aseptic by boiling.

9. Several sizes have been made, so that in conjunction with Hank's or Peesley's sounds all ordinary work can be done.

10. The cost is about the same as for the divulsor made without the irrigating tube.

10 West Thirty-sixth Street.

A Leper Colony was recently established at Villuisk, in eastern Siberia. At present the lepers are housed under tents, but huts are to be built for them in the spring, and the government has granted the settlement an annual subsidy of $3,500, which will enable provision to be made for one hundred lepers. At present there are about forty lepers in the colony.

A CASE OF INTERMITTENT HYDRONEPHROSIS.

By GEORGE H. GOODGER, M.D.,

DAVISBURG, MICH.

Intermittent hydronephrosis is a diseased condition which is so seldom reported and encountered that I desire to call attention to the following case. I am of the opinion, also, that it is more frequently seen than recognized, as the case herein detailed was under the observation and treatment of several physicians before I saw it, and none had given a proper diagnosis. They had called it enlarged and displaced spleen, impaction of the colon, enterolith, ovarian tumor, and movable kidney.

Mrs. F. M——, aged forty-five, mother of four children, youngest twelve years of age. Has a very pronounced dejena, which began when she was fourteen years of age. Complains of pain in left side and a tumor which "comes and goes." First noticed the lump three or four years ago, which has gradually grown in size at each successive appearance. The attacks have grown progressively more frequent, until now she has an attack every week, with extreme regularity. No history of injury at or shortly before the time of first appearance of the tumor, although she states that for a year or two prior to that time she suffered periodical pains in the left region of abdomen and in region of left kidney. Can foretell an appearance of the tumor, some hours before it becomes visible, by pain in back and region of left kidney, followed by the gradual appearance of the tumor in the left lumbar region. When tumor is forming urination is frequent, but only very small quantities are passed at a time, and the aggregate amount is much less than normal. Recollects that when tumor disappears unusually large quantities are voided. During attacks vomiting is severe and persistent, and constipation is present; when tumor disappears bowels become relaxed and much mucus is passed per rectum, but no lumps of hardened fæces. During intervals of attacks she is comparatively well and does her own housework.

August 10, 1894.—Examined tumor to-day and found it occupying left abdominal region, reaching from near the umbilicus to the crest of the ilium, and upward under the short ribs. It is not lobulated, but rounded in outline, firm in consistence, and dull on percussion. Pressure produces a peculiar sickening feeling and a desire to urinate. The tumor does not move on inspiration, but when ribs are drawn upward the edge of the hand can be inserted between them and the tumor. The tumor is plainly visible when lying on back or standing, and becomes more so when lying on right side, when it falls toward the mesial line, and causes a dragging sensation. Supporting it in this position gives relief. Urination last twenty-four hours has been frequent but scanty.

August 11th.—Examined the tumor again to-day and no change is apparent, except that it is larger. Instructed the attendants to measure quantity of urine passed till next visit and save some for analysis.

August 12th.—The tumor has disappeared. They had not measured the quantity of urine, but described it as large; from description I judged two quarts or more during the night and early forenoon. They reserved some, however, for analysis, and upon examination it was found as follows: Sp. gr., 1.012; no albumin; no sugar; pale color and normal odor; no sediment to speak of and no pus; reaction neutral. No microscopical examination was made.

I made the diagnosis of intermittent hydronephrosis, and ordered a pad made and worn over left lumbar region. At last accounts this was producing some amelioration in the way of lessening the frequency and also the duration and severity of the attacks. As the patient lives at a great distance I have not seen her since the pad was first worn and do not know, defi-

nitely, the amount of improvement which has taken place.

Now, as regards the diagnosis there are, according to Osler,[1] the following points in well-developed cases: "Pains; the development of a tumor in the flank; its disappearance, usually with an increase in the amount of urine." These symptoms should suffice to exclude any of the conditions for which this case was mistaken. The cause is often obscure, and in this case I was unable to determine positively the cause.

Ferrier and Baudoin[2] have collected eighty-three cases and found the usual cause to be movable kidney, which, owing to its displacement and loose attachment, allows the ureter to become twisted, thus occluding its lumen, and causing a damming up of the urinary secretion.

I think that the cause in my case was movable kidney, but if that were the only cause, I am unable to account for the regularity with which the attacks occur.

HERNIOTOMY, McBURNEY'S METHOD, IN JAPAN.

By CHARLES F. STOKES, M.D., U.S.N.,

LATE HOUSE SURGEON TO BELLEVUE AND GOUVERNEUR HOSPITALS, NEW YORK.

J. G——, porter, aged forty-five, native of Portugal, was admitted to the United States Naval Hospital, Yokohama, Japan, for operation, and gave the following history:

Seven years ago, while performing his duties as porter, he acquired a left scrotal hernia, which was reducible by taxis until three weeks before admission. Not being able to secure an efficient truss, the gut was allowed to remain unreduced, and was, in consequence, subjected to hard knocks and rough treatment, incident to his calling. On several occasions, after powerful efforts at lifting, or as a result of traumatism, he had acute pain in the part, which usually passed off within forty-eight hours. Four weeks before admission, he had an attack of influenza, with severe paroxysms of coughing. These considerably increased the size of the hernia, which became the seat of sharp, knife-like pains, as did also the abdomen, in the left inguinal region; at the same time he had distressing dyspnœa, hiccough, and could retain little or no food. The writer saw him in consultation with Dr. C. H. H. Hall, his physician, when taxis was tried, under ether anæsthesia, without success.

He was admitted to the hospital, November 1, 1893, when he stated that he had lost twenty-five pounds in four weeks. His expression was anxious; he had constant hiccough, and refused food. He was pallid and emaciated, and suffered from intense dyspnœa and constant pain in the left groin. The pain and dyspnœa were relieved only when he assumed the knee-chest position, in which position he would remain until forced to recline from sheer exhaustion. He had an incessant, dry, nervous cough, which added to the pain.

Careful chest examination elicited no abnormality in the lungs. The heart sounds were scarcely audible; a faint systolic murmur was heard in the region of the apex. The intestines were moderately distended with gas, and there was pronounced tenderness in the neighborhood of the internal abdominal ring. A large, oblique, irreducible, inguinal hernia occupied the scrotum on the left side. It gave the impression of being largely made up of omentum. Bowels responded to cathartics. Urine examination, negative; temperature, subnormal; pulse, weak and slightly accelerated; respirations ranged from 32 to 34 per minute. The dyspnœa, hiccough, and vomiting were thought to be reflex in character, while the local symptoms were due to some pathological condition of the contents of the sac.

Operation November 3, 1893. The writer was assisted by Surgeon F. Rogers, U. S. N., and Drs. C. H. H. Hall and W. Van der Heyden. Ether anæsthesia was used. Close attention was given to rendering the field of operation, hands, instruments, and dressing aseptic. A free incision along the line of the hernia, involving the superficial tissues, was made. The sac was freed at the external ring, the fibres of the upper wall of the canal were divided down to the internal ring, and from this point the sac, which was densely adherent, was dissected out. The dissection was most difficult and tedious, as the cord was firmly attached to it. When freed, the sac was opened on its anterior aspect by a linear incision, and was found to contain eighteen inches of the large intestine. Firm adhesions bound the intestine to the sac and to the parietal peritoneum adjacent to the internal ring. These were broken down with the fingers, and divided with scissors. Beyond the adhesions, there was nothing to account for the profound reflex symptoms noted above. The internal ring readily admitted the ends of the thumb and four fingers. The gut was reduced, and the sac tied off with a silk ligature, well within the internal ring, to avoid dimpling, and cut away three-fourths of an inch below the ligature. The skin edges above were sutured to the edges of the divided canal, on their respective sides, and below were brought together with catgut sutures, after introducing a rubber drainage-tube. The unclosed portion of the wound above was snugly packed, well down to the peritoneum, with iodoformized gauze; over this, covering the entire wound, aseptic gauze and absorbent cotton were applied, supported by a snug spica bandage. The patient was under ether somewhat over three hours. He reacted badly, and considerable stimulation was necessary.

November 8th, five days after the operation, the dressings were removed. The wound was aseptic. Primary union had taken place where the skin edges were approximated. The drainage-tube was removed. Balsam of Peru gauze was substituted for the iodoformized, as it was thought the patient had absorbed a toxic amount of iodoform; otherwise, the dressing was the same as applied originally. The highest temperature recorded was 99.9° F., the day after the operation. Dressings were also made on November 14th, 20th, 24th, 28th, and December 5th, when the wound, which had remained aseptic throughout, was solidly healed, and all dressings were discontinued.

The immediate effect of the operation was most gratifying. The cough, dyspnœa, hiccough, and vomiting ceased, while locally no pain was experienced. Food, in small amounts, was relished. It was with difficulty that the patient, who was impetuous and intractable, was kept in bed during the healing of the wound.

Toward the end of the fourth week, he complained of pain in his left side, had a moderate rise of temperature, cough, with blood-tinged sputum, and albuminous urine. A patch of consolidation was found in the lower lobe of the left lung, which was at first thought to be a pneumonic process, but later unmistakable signs of acute tuberculosis developed. The room used by the patient had been recently plastered and painted, and he was the first person to occupy it thereafter. He was up and about after December 5th, when his lung lesion would permit, and wore no truss or other support during the remainder of his stay in the hospital. The new cicatrix was put to the test by an almost incessant cough. At no time was there a vestige of a recurrence of the hernia. He left the hospital, January 13, 1894, to seek treatment for his pulmonary trouble elsewhere. He died four days afterward, and although an autopsy was earnestly desired, it could not be obtained.

The case is instructive, in so far as it shows that a very young cicatrix may be trusted to guard an excep-

[1] New York Medical Journal, July 28, 1894.
[2] Annual of Universal Medical Sciences of 1893.

tionally large ring, if the operation be properly performed. The secret of success, so clearly pointed out by McBurney, lies in avoiding dimpling of the peritoneum after ligating the sac, and in insuring granulation from the peritoneum out. The pronounced reflex symptoms recorded, and their immediate cessation after the gut was freed and returned to the abdomen, are of exceptional interest. No signs of strangulation or obstruction were observed.

So far as can be ascertained, this is the first time McBurney's method has been practised in progressive Japan.

Progress of Medical Science.

The Diagnosis of Diabetes and Glycosuria by Examination of the Blood.—Dr. Bremer describes a modification of Ehrlich's method of staining cover-glass preparations of blood with eosin and methyl blue. By this method of staining, in normal blood the red blood-corpuscles appear brownish red, but the color varies from a clear reddish brown to a deep chestnut brown (*The British Medical Journal*). The nuclei of the leucocytes stain blue. Bremer found that in diabetes and glycosuria the red blood-corpuscles either remained completely unstained, or they were simply tinted light yellow or greenish yellow. Only occasionally a small peripheral zone of the red corpuscle was tinged slightly red. Other minor changes were found in the leucocytes. With acid fuchsine and other so-called acid dyes, the red corpuscles of diabetic blood stained just in the same manner as those of normal blood. It was only eosin which did not stain them. In order to determine whether this loss of staining affinity for eosin was due to the abnormal amount of sugar in diabetic blood, Bremer treated cover-glass preparations of normal blood with a solution of sugar. But he found that the red corpuscles still stained with eosin, as in normal blood. If, however, a cover-glass preparation of non-diabetic blood was floated for twenty-five to thirty minutes in a diabetic urine, the red corpuscles failed to stain brownish red with eosin; they remained unstained or were only slightly tinted yellow or greenish yellow, as in diabetic blood. But the red corpuscles in a cover-glass preparation of non-diabetic blood, treated with urine free from sugar, stained well with eosin. In glycosuria produced artificially by the administration of phloroglucin for three days, the red corpuscles failed to stain with eosin, as in diabetes.

Is Iodoform an Antiseptic?—Most practical surgeons would unhesitatingly say "Yes" to this question. Heyn and Roosing showed, however, in 1887, that the presence of iodoform on gelatine plates did not impede the growth of colonies of microbes, such as the staphylococcus aureus, the pneumococcus, etc. They likewise stated that a plug of iodoform gauze introduced into the vagina of a healthy woman abounded, on its extraction, with bacteria. M. Stchegoleff has recently reinvestigated this question in the laboratory of Professor Strauss, of Paris (*The Lancet*). He found that beef-peptone-gelatine bouillon, which is an excellent culture medium for Koch's tubercle bacilli, loses that property when it has incorporated with it five per cent. of iodoform, the tubercle bacilli sown in it dying in forty-eight hours. When an emulsion of virulent culture of tubercle bacillus and ten per cent. of iodoform was employed to inoculate guinea-pigs, the animals survived longer than those that had received non-iodoformed inoculations. Thus iodoform kills the bacilli in the cultures, but only attenuates their virulence when introduced into the system at the same time as the tubercle bacillus. The action of iodoform on the staphylococcus is just the reverse of what it is in the case of the tubercle bacillus, for that micro-organism (the staphylococcus) flourishes in an iodoformed culture medium, while the inoculation of the staphylococcus previously submitted to the action of the drug is inoffensive. From 1½ c.c. to 2 c.c. of iodoformed culture could be injected with impunity, only a trifling local reaction being produced, whereas other animals inoculated with the staphylococcus grown in ordinary media were affected with abscesses or died in a few days from septicæmia. When, however, the iodoform is mixed with the staphylococcus at the moment of inoculation a small local abscess results, showing that there is only attenuation and not suppression of the virulence. M. Stchegoleff thought that perhaps the iodoform, while not attacking directly the staphylococcus, acts, nevertheless, on the toxine secreted by the microbe. To determine this point he prepared two kinds of culture—one normal and one mixed with ten per cent. of iodoform. A week later he filtered them in order to deprive them of living organisms, and then inoculated rabbits with them. Those inoculated with non-iodoformed toxines died in a few hours, whereas the animals inoculated with the iodoformed toxines remained well. M. Stchegoleff opines that under the influence of iodoform the toxines of the staphylococcus are converted into non-poisonous iodized compounds. We can now understand how iodoform applied to a sore prevents suppuration and infection without killing the pyogenic organisms. Löffler's diphtheria bacillus is affected by iodoform in much the same way as the staphylococcus. It grows well in an iodoformed culture medium, but its virulence is diminished. The diphtheria toxines are weakened, and even altogether neutralized, by iodoform, provided the drug is present in adequate proportion and for a sufficient length of time.

Physical Signs of Acute Pericarditis.—According to Dr. Josserand the friction sound in pericarditis is often in arrear of the anatomical evolution of the disease, not being present until a longer or shorter period has elapsed. The following is, in his opinion, an early sign of real value. When, in the course of an acute articular rheumatism, comparative auscultation is made at the cardiac base in the aortic and pulmonary areas, it sometimes happens that the second sound in the pulmonary area is found to be more intense, louder, and more metallic; the opposite is the case in chronic aortitis, in which the sound is more marked on the right side of the sternum than on the left. Sometimes even this difference is appreciable by the hand, which perceives an exaggeration of the diastolic closure shock of the pulmonary sigmoid valves. The existence of this sign should cause one to search carefully for a friction sound, which will then often be considered when a superficial auscultation would have allowed it to escape notice; if not present, its more or less early appearance may be predicted. This noisiness of the second sound is early and usually transitory; it precedes the friction sound by from one to three days, and with few exceptions, is replaced by it. It is a sign proper to the initial congestive period, like the fine crepitation of pneumonia. Its anatomical explanation is, Josserand thinks, that the heart muscle at the base of the pulmonary artery is rendered congested, turgescent, more dense, and perhaps covered with fibrinous lymph, and thus amplifies to the ear the neighboring sigmoid sounds. This sign is important, first, in diagnosis, to enable one to decide between a friction sound and an anæmic murmur or extracardiac sound, as it permits one to decide in favor of the friction sound; secondly, as a sign that the heart is affected, with localization and intensity difficult to state precisely. It indicates the necessity for early revulsive medication.—*La Semaine Médicale.*

Is Simple Stricture of the Rectum in Reality Syphilitic?—The Paris correspondent of *The Lancet* writes that M. Verneuil had recently under treatment a man, aged sixty-eight years, pale, thin, and cachectic, who

complained of a swelling of the anal margin which had, it appears, reappeared for the fourth time. M. Verneuil, imagining he had only to deal with a simple subcutaneous abscess, opened it by means of the thermo-cautery. All seemed to go well both locally and generally with the patient until the twentieth day, when the healing process was arrested, and a thin serous discharge appeared. This led M. Verneuil to make a second wrong diagnosis (urinary abscess), and a urethral stricture from which the man suffered was treated by progressive dilatation. The thin discharge continued, however, and sharp pains were complained of in the neighborhood of the wound, the edges of which became prominent. Defecation was difficult, the abdomen became tympanitic, and appetite and strength disappeared. Further examination revealed the presence of an ano-rectal gumma with stricture of the rectum, the man confessing to having had a penile chancre with the usual secondary sequelæ in 1888. Specific treatment, without any further surgical proceedings, brought about a rapid cure, the gumma soon being absorbed. M. Fournier regards this case as a confirmation of his views regarding the nature of simple or fibrous rectal stricture —viz., that it is always syphilitic. This idea has been contested on the ground of the usual inefficacy in these cases of specific treatment. According to M. Fournier failure is due to the treatment being applied too late, when sclerosis has done its work. He calls attention to these cases where, with a rectal stricture, there exist ano-rectal and ano-perineal lesions, the gummatous nature of which can be recognized *de visu*, especially when these lesions are ulcerated. In such cases regular anal fistulæ may develop (syphilitic fistulæ, described by the late Professor Trélat). M. Le Dentu, although he has only met with one success from the specific treatment of stricture of the rectum, concurs with M. Fournier's views as to its (so-called simple stricture) syphilitic origin.

The Treatment of Cancer of the Stomach by Sodium Chlorate and Aristol.—Dr. Huchard has employed sodium chlorate in daily amounts of from 150 to 180 grains dissolved in from 5 to 7 ounces of water in divided doses, so that a continuous topical action of the salt may be maintained, not only upon the tumor but also upon the gastric mucous membrane. If larger doses are used symptoms of gastric irritation supervene, and the remedy can no longer be borne. To definitely state if this be a curative agent, many years of observation are needed ; it can, however, be stated that sodium chlorate in large doses has a very favorable action upon functional disturbances of the stomach. It increases the appetite, diminishes pain, makes the vomiting of food to disappear, and causes the hæmatemesis to cease. Aristol has been found to be inferior to sodium chlorate, but is useful, if the stage of ulceration has been reached, because it appears to possess a local action in the digestive canal when given in pill-form, in doses of three or four, of one and one-half grain each, daily. These remedies should be used, at least, because they relieve the functional disturbances.—*Journal des Practiciens.*

The Treatment of Stridulous Laryngitis in Children.—M. Huchard remarks that the opinion that stridulous laryngitis in children is always a benign disease should not be credited too much. Trousseau cited cases in which tracheotomy had to be performed, and M. Huchard himself has observed the case of a child in whom cyanosis and asphyxia were so intense that tracheotomy had to be done. In other cases coming under his observation surgical intervention had not been resorted to, although the intensity of the symptoms had been remarkable, the laryngeal spasms occurring nearly without remission for three consecutive days and nights ; the voice had been nearly inaudible, and dyspnœa and cyanosis had been considerable. M. Cadet de Gassicourt has also reported similar cases. Finally, in a recent thesis, M. Touchard has made a *résumé* of some interesting facts and divided them as follows : 1. Cases in which tracheotomy had been performed, with recovery. 2. Cases in which death had resulted because tracheotomy had not been performed. 3. Very serious cases in which surgical intervention had not been necessary. 4. Benign cases where *tirage* had existed, but with less intensity of the symptoms. M. Huchard does not discuss the question of whether or not this affection is the result of transitory tumefactions of the glottic mucous membrane, if it is due to mechanical stenosis caused by the accumulation of mucus near the glottis, or if this laryngitis is first localized in the subglottic portion of the larynx. It is known, he says, that stridulous laryngitis is composed of two elements, inflammation and spasm of the larynx, and the danger in these cases is the spasm and not the inflammation, which may be slight or intense without increasing the gravity of the case. Before surgical intervention is resorted to, however, early medical treatment should be instituted. M. Huchard does not hesitate to prescribe sixty or even seventy-five grains of potassium bromide a day for a child four and a half years of age given in large doses ; it is important, however, that these doses should be given in the beginning, without fear of toxic accidents, in order to insure prompt and sure sedation of the glottic reflexes. This treatment must be continued for from five to eight days at the least, for clinical experience has shown that the attacks of false croup may be repeated for several nights. Such is the necessary medical treatment of stridulous laryngitis, whether benign or serious. With regard to surgical intervention, one must resort to the last extremity when all medical means have been exhausted, and when there is danger of asphyxia. The two methods of surgical treatment are tracheotomy and intubation of the larynx. It must not be forgotten, says M. Huchard, that during measles very serious forms of acute laryngitis, which simulate croup, may be observed at three periods : in the beginning, when the eruption appears, and during convalescence.—*New York Medical Journal.*

Convulsions of Childhood.—Dr. Chenbach, of Bucharest, has recently made a clinical and experimental study upon this common complication of early life. Following the earliest experiments of Feltz and Ritter, and the more recent ones of Bouchard, the author has carried out a series of experimental studies by injecting the urine of epileptic subjects into the circulation of the rabbit. The conclusions which he has arrived at from this portion of the work are as follows : 1. The urine of convulsive affections, filtered and introduced into the circulation of rabbits, produces clonic and tonic convulsive manifestations. 2. These convulsions appear more rapidly, and are more violent than those produced by normal urine. 3. Prolonged boiling diminishes, in part, the toxicity of the urine, and modifies the toxines contained in it. 4. The presence of convulsivant substances in the urine of convulsive affections appears to be proven. 5. Bromide of potassium employed in the treatment of such affections, being introduced into animals with the urine containing it, diminishes, or even prevents, such convulsions. 6. In convulsive affections of children the urine shows a more energetic and prompt action than that of adults under the same conditions. In the clinical study especial attention is paid to the convulsions appearing in the course of the infectious diseases. His conclusions are as follows : 1. It is to be admitted as probably the fact that convulsivant substances are found in the organism and produce auto-intoxication. 2. Such auto-intoxications give the most satisfactory explanation of the production of convulsive phenomena in children during or following infectious diseases. 3. Alterations in the liver, by diminishing its antitoxic activity, favor auto-intoxication, and, consequently, the appearance of convulsions.—*Revue mensuelle des Maladies de l'Enfance.*

WM. WOOD & CO., 43, 45, & 47 East Tenth Street

New York, May 18, 1895.

IRON AND SUGGESTIVE THERAPEUTICS.

IT would seem as though the last word had been said about iron (*ferrum*) from spectroscope and test-tube to drug-store and bedside. But this was the subject selected for discussion at the recent meeting of the German Congress of Internal Medicine, and, after looking over the papers read, we confess that the topic was not unwisely chosen.

Professor Bunge, of Basel, who opened the debate, in particular, stated some facts which ought to be known by all practitioners.

The human body, he said, contains a considerable amount of iron, this amount varying from thirty to forty-five grains (2 to 2½ gm.). This iron is chiefly found in the hæmoglobin of the blood, in the form of proteid compound. Physicians, he says, generally suppose that the iron which they prescribe medicinally is taken up and applied to the building up of this compound. But this, says Bunge, is a mistake, for recent experiments make it extremely probable that the inorganic iron preparations are not at all absorbed. Thus, Hamburger, in experiments upon animals, was able to collect from the fæces all the iron administered by the mouth. The same results were obtained by Schmiedeberg and his pupil, A. Marfori. There is practically no inorganic iron in the urine. If one administers iron, this barely perceptible trace in the urine is not increased. If iron is not excreted by the urine, the only way in which it can leave the economy is by the intestines, and experiments show that as a matter of fact the body-iron is lost in this way. Bidder and Schmidt established this fact by experiments upon starved cats. They found ten times as much iron in the fæces as in the urine. The same results have been reached by experiments on fasting men. Further experiments show that iron is excreted, not by the stomach or through the bile, but by the intestines.

Voit, Marfori, and Hamburger have all shown that inorganic iron compounds are not absorbed in an appreciable amount by the alimentary tract. Bunge comes to the conclusion that iron is only taken up and used to make hæmoglobin in some peculiar organic form. In order to discover what this form was, Bunge made chemical experiments with the yolks of eggs. This substance must contain some iron preparation which is capable of building up hæmoglobin, since, as the chick grows, blood is manufactured out of the nutrient substance of the yolk. He discovered this substance to be a nucleo-albumin, and named it hæmatogen because it is the substance (*Vorstufe*) out of which hæmoglobin is built.

Bunge assumes that our daily food contains this hæmatogenous substance, and he is led to the conclusion that iron is best taken into the economy, and perhaps only so taken, when given in its natural combination in the food. In examining milk for the purpose of finding its hæmatogen he was surprised at the very slight amount of iron in this so-called perfect food. The amount of iron in milk is six times less than that of the tissues of new-born animals. How, he asks, are we to explain the fact that new-born animals are supplied with such iron-poor food? The explanation is that the new-born contain an excess of iron stored up in their tissues, and this lasts them until they are weaned. In rabbits, for example, he found eighteen grammes of iron at birth and only one-sixth this amount three weeks later. In babies he assumes that the same relations exist, and he calls attention to the fact that since milk is a food so poor in iron, it should not be given for a protracted period either to babies or adults. The clinical fact that milk is bad as an exclusive diet in anæmia was confirmed by one of the speakers in the discussion which followed.

Bunge's subsequent remarks were confined to a consideration of the absorbability and assimilability of the officinal preparations of iron. Bunge is inclined strongly to disbelieve in the real value of these preparations. He states that even iron which is absorbed is not necessarily assimilated. On the other hand, he says that in about ten days the ordinary food will convey to the organism iron equal to one-third that in the blood. In other words, the food contains always enough iron to supply the needs even of the very anæmic.

The apparent utility of iron in therapeutics, he thinks, is largely a matter of suggestion.

THE STATE INSANE ASYLUMS AND THE STATE POLITICAL MACHINES.

THE report of the sub-committee of the joint legislative committee which has been investigating the State Commission in Lunacy has presented its report.

This report commends the work of the State Lunacy Commission and urges an increase of its powers, with a corresponding decrease of the powers of the local managing boards. The report says:

"The functions of the local managers have gradually diminished, and their usefulness, except in a visitorial sense, may well be questioned. If retained at all, they should be of uniform number, not exceeding five; should reside in the immediate vicinity of the hospital, be appointed by the Supreme Court of the district, and be debarred from holding any legislative or State executive offices. It is a further impeachment of the present method in vogue for procuring special appropriations that, despite the large sums annually voted, the necessary repairs and improvements have not kept pace with the outlay."

Of course this means practically that the entire man-

agement of all our State Asylums shall be placed in the hands of three men with an office at Albany. These men will have the power of appointments, of purchase of supplies, awarding contracts, and all the immense patronage connected with the care of over fifteen thousand insane. It is easy to see of what value this scheme might become to the dominant party and its machine politicians. We cannot believe that such a scandalous recommendation will receive serious attention.

DOCTORS AND MANAGING BOARDS.

The Mayor of this city failed to appoint a medical man on the Board of Commissioners of Charities and Correction. We have no fault to find, though it is regrettable that some physician could not be found to sit on a Board which has to deal so much and so entirely with the sick. We presume one reason is that a medical man of the experience and character needed for so important a position cannot easily be got for the sum of $5,000 a year.

While the Mayor's action is a disappointment it is not half so keen as that which the profession will feel if the bill to allow a physician to be President of the Board of Health fails to become a law. We trust that this measure will be vigorously urged by the medical profession throughout the State. The present law is an insult to the intelligence of practitioners of medicine.

FOUR YEARS' MEDICAL COURSE.

We have always advocated the highest and most rational methods of medical instruction, but we have not considered it necessary or possible to lay down hard-and-fast rules as to what these methods shall be. There is no doubt that four years is not too long a time to study medicine, yet there are many cases in which four years of college study are not needed. If a young man has spent four years in getting a degree of A.B. or B.S., if he then studies medicine three years, and at the end of that time enters a hospital for a year and a half he should be as well equipped to practise medicine as educational institutions can make him. There should, therefore, in our opinion, be concessions made to those medical students who have at the end of three years become hospital internes. This degree may be withheld, perhaps, or given conditionally, but three years is long enough for intelligent, well-educated men to learn the didactics of our art. To force upon them another year in addition to the hospital course may often prove an unnecessary hardship.

There is developing a kind of four-year-course fanaticism among some of those who are in the propaganda for higher education. A previous college training and a year and a half in a hospital ought to entitle a man to get off with only three years of lecturing and reciting.

Hydrotherapy for the Poor.—The Riverside Association of this city has established free baths for the use of the poor. The new institution contains a complete equipment for the use of hydrotherapy, under the supervision of Dr. S. Baruch.

News of the Week.

The American Academy of Medicine held its annual meeting, under the presidency of Dr. J. McFadden Gaston, of Atlanta, in Baltimore, on May 4th and 6th. Dr. J. E. Valk, of Philadelphia, read a paper on the "Limits of a Physician's Duty to the Dependent Classes." He said that the physician should remember that he is a man and a citizen, as well as a pathologist and therapeutist. He held that physicians should not be expected to give their services to public institutions, for they were already taxed for their support, and if they served free they made a double contribution. He also advocated a reform of the dispensary abuse, which he thought might be brought about by the very growth of the evil, the enormity of which would eventually lead to its destruction by an awakened public and professional sentiment. Dr. W. L. Estes, of South Bethlehem, Pa., presented a communication on "Hospital Management," in which he advanced the very sound doctrine that of the two boards connected with a hospital the medical board should be higher and more authoritative in its action than the lay board of managers. The superintendent, who is a connecting link in this dual management, is usually a layman, but he should be a physician. Dr. W. L. Pyle, of Washington, presented a "Plan for an Emergency Hospital." Such a hospital, he said, should be easily accessible, on a street of some width, in convenient communication with a police station. There should be a sheltered driveway for the ambulance, communicating by large doors with a large, airy room, kept constantly in readiness for any operative procedure. An emergency ward should adjoin this room, and some padded wards for alcoholics, the acutely insane, etc., should also be found on this floor. The administration should belong to the municipal authorities, having an advisory board of physicians and surgeons. Dr. Emma B. Culbertson, of Boston, read a paper on the reform of the dispensary abuse, giving an outline of the plan followed by the New England Hospital for Women, in which those applying for relief were investigated by the "United Charities." Dr. George M. Gould presented a communication on "Hospitalism," in which he defined the dispensary disease, or hospitalism, as "a contagious, epidemic, ingravescent neurosis of civilization, limited as regards time to the present, and as regards geographic distribution to the urban population. It attacks three considerable classes—the professional philanthropist, the commercial physician, and the social sponge." He detailed the symptoms of the disease as manifested in the endowing class, the patient, and the physician. There is no specific remedy for the affection and we must employ every means at our hand that may promise a slight degree of relief. The prognosis is very grave, and the cure of the disease cannot be looked for in our day. Dr. Bayard Holmes, of Chicago, also read a paper on medical charities, in which he said that the endowment of charities is inexpedient. The medical profession is in great measure to blame for what it has to endure from the lay management of charitable institutions. Dr. Woods Hutchinson, of Des Moines, read

a paper on the "Economics of the Social Evil." He thought the youth of the land should be properly taught the dangers of fornication with prostitutes, and said that if then they chose to incur the dangers it was at their own risk, and society would be well rid of them when they were exterminated by the diseases which they brought upon themselves.

The first paper on Monday, May 6th, was by Dr. Delancey Rochester, of Buffalo, upon the "Proper Teaching of Physiology in Public Schools as a Means of Preventing Intemperance and Disease." The speaker advocated the teaching in schools of the physiology of the sexual organs as well as that of digestion. This could be done without going into unnecessary detail. Children will learn such things for themselves, and it is better that they should be taught them seriously. The evils of the abuse of alcohol and tobacco should also be pointed out. The annual address of the President was read by Dr. J. McFadden Gaston, of Atlanta, who took for his title "Rudimentary Preparation Compared with Higher Education for Specialties in Medicine and Surgery." In the evolution of specialism, he said, it may be anticipated that little or nothing will be left for the occupation of the general practitioner, and it becomes a grave question as to the final outgrowth of this division of labor to such an extreme degree. He held that the *rôle* of the general practitioner is essential for the advancement of medicine and surgery. It will prove disastrous to the best interests of the medical profession if all practical work is parcelled out into these subdivisions. The curriculum of instruction in medical schools should be maintained so as to qualify their graduates for entering upon general practice in medicine and surgery. There should not be any provision in the graded courses of three or four years for turning out specialists, but the preparation for a specialty should not begin until after graduation and a certain exercise in general practice. Dr. E. F. Wilson, of Columbus, O., read a paper entitled "Is the Recitation Method of Teaching a Success in Medical Colleges?" He answered this question in the affirmative, claiming as advantages for the recitation method: 1. The students do more and better work. 2. By using recent text-books the students receive the latest and best teaching of the master-minds of the profession. 3. There is no break in the method of study in the change from the college to the medical school. 4. A better preliminary education will be required. 5. It will, in time, cause the medical course to be regarded as a post-graduate course. 6. It enables the student to ask questions and thus have obscure points made clear. Papers were also read by Dr. Millard, of St. Paul, on "A Plea for Efficient Medical Legislation;" by Dr. Peterson, of Grand Rapids, on "The Need of more Medical Reference Libraries, and the Way in which They can be Established;" and by Dr. Grosvenor, of Buffalo, on "What shall we Do with our Alcoholic Inebriate?" The election of officers for the ensuing year resulted in the choice of the following: *President*, Henry M. Hurd, M.D., Superintendent of Johns Hopkins Hospital, Baltimore; *Vice-Presidents*, Woods Hutchison, M.D., of Des Moines, Ia.; John B. Roberts, M.D., of Philadelphia; Emma B. Culbertson, M.D., of Boston; W. F. Southard, M.D., of San Francisco. *Secretary and Treasurer*, Charles McIntire, M.D., of Easton, Pa. *Assistant-Secretary*, Edgar Moore Green, M.D., of Easton, Pa.

Preparation and Sale of Therapeutic Serums in France.—The following is the text of the law in France relating to the preparation, sale, and distribution of therapeutic serums and other analogous products, promulgated on April 25th last: Article 1. Attenuated virus, therapeutic serums, modified toxins, and analogous products that may be used for the prophylaxy or therapy of contagious diseases, and injectable substances of organic origin not defined chemically, that are applied to the treatment of temporary or chronic affections, shall not be distributed gratuitously or otherwise unless their manufacture or place of origin shall have been the object of an authorization of the Government given with the sanction of the Consulting Committee of Hygiene of France and of the Academy of Medicine. Such authorization shall be temporary and revocable. The said products shall be submitted to the inspection of a commission appointed by a competent minister. Art. 2. These products shall be delivered to the public by pharmacists upon medical prescription. Each bottle or receptacle shall bear the mark of its place of origin and the date of its manufacture. In urgent cases physicians are authorized to furnish their patients with the said products. When the said products are destined to be delivered gratuitously to the poor the vials containing these products shall bear, stamped upon the glass, the words, "Public Assistance, Free." They may then be deposited, under the control of a physician, at such establishments as may be authorized by the administration to procure these products direct. The foregoing provisions shall not apply to Jennerian vaccine, either human or animal. Art. 3. The sale and distribution of the substances mentioned in Art. 1 shall be regulated by and come within the provisions of Art. 423 of the Penal Code and of the law of March 27, 1871. Any fraud as to the nature of the said substances, knowing them to be falsified or adulterated, or any fraud or attempt at fraud in regard to the quality of the article delivered, will be punishable in accordance with the provisions of Art. 423 of the Penal Code and of the law of March 27, 1871. Art. 4. Any infraction of the present law will be punished with a fine of from 16 to 1,000 francs.

Preliminary Training for Students of Medicine.—Governor Morton has approved the bill of Assemblyman Horton providing that candidates to study medicine must have completed a full instead of three years' academic or high-school course to obviate the necessity of taking regents' examinations.

The Medical Society of Pennsylvania will hold its forty-fifth annual meeting at Chambersburg, Pa., May 21st to 24th.

Hypnotism.—The author of the article on hypnotism in our recent issue should be Chalmer Prentice instead of Charles Prentice.

The Microscopical Society of Washington, D. C., gave its annual reception on the evening of May 13th at the National Rifles Armory. Many interesting exhibits were made by the different members.

The Case of Medical Inspector Edward Kershner, U. S. Navy, to which allusion has been made in a previous issue of the MEDICAL RECORD, is before a court-martial convened at the Brooklyn Navy-Yard. It will be recollected that Inspector Kershner declined to visit a sick man on a neighboring vessel lying off shore, as he did not wish to jeopardize his own crew while help could be easily obtained from shore. For this he was charged with inhumanity in disobeying the orders of his superior officer, and in subsequently reporting the case to the newspapers. To these charges he pleads not guilty. An important question to be settled will doubtless bear upon the fact whether or not a commander has jurisdiction outside of his ship and can order any officer to extra duty accordingly, or place the safety of a crew against that of a single individual.

Typhoid in Stamford and New Milford, Conn.—Dr. Frederick Schavoir, the new health officer of Stamford, reports that of 337 cases of typhoid occurring in that town, 307 have been traced to the milk-supply, already referred to in the MEDICAL RECORD. The epidemic is supposed to have reached its height. A committee has been appointed to inspect the sewers and make the necessary repairs and alterations. The daily papers contain accounts of a similar epidemic of typhoid fever which is prevailing in New Milford. The disease is said to have been distributed by milk obtained from a certain farm in the neighborhood. Up to May 9th, 23 cases had been reported.

Bellevue Hospital Medical College.—At the annual meeting of the Faculty of Bellevue Hospital Medical College the following changes were made: The title of the Chair of Dr. Joseph D. Bryant was changed so as to be, Professor of Anatomy and Operative and Clinical Surgery. Dr. George D. Stewart resigned as one of the Demonstrators of Anatomy and was appointed Director Adjunct in Anatomy, under the direction of Professor Bryant. Dr. George D. Stewart was Nominated Assistant Visiting Surgeon to Bellevue Hospital. Dr. H. M. Silver resigned as Demonstrator of Anatomy. Dr. John F. Erdmann was appointed Professor of Practical Anatomy and put in charge of the dissecting-room. Dr. Winfield Ayres, Dr. William C. Lusk and Dr. John J. Rothwell were appointed Assistant Demonstrators of Anatomy. Reginald H. Sayre was appointed Lecturer Adjunct in Orthopedic Surgery. Dr. Austin Flint, Jr., was elected Professor of Obstetrics. Dr. William H. Park was appointed Instructor in Contagious Diseases.

Dr. A. E. Davis Gets a Verdict Against a Newspaper for Malicious Slander.—Dr. A. E. Davis, of this city, as a result of a suit for libel against the *Sun* Printing Association obtained a verdict in his favor for $2,500. The action was based on two articles published in the *Evening Sun* on February 11 and 13, 1893, one of them headed "Scandals Galore," over several other head-lines of equally startling import. The article, which was more than a column long, gave a flippant account of trouble in a boarding-house at No. 463 Fifth Avenue, which was apparently started by the prying and gossiping of an old woman. The plaintiff charged that the article made false insinuations as to his conduct. The matter first acquired publicity through a charge of assault made in a police court against Dr. Davis by a Mrs. Ashley, which was dismissed. We congratulate the plaintiff on his vindication. The moral character of a physician is always very dear to him and should be protected at all hazards.

Obituary Notes.—Dr. CHARLES SUTHERLAND, Surgeon-General U. S. Army, died in Washington on May 11th, aged sixty-six. He was brevetted colonel in March, 1865, for meritorious services during the Civil War. He then served in Washington, New York, and San Francisco until 1884, when he became Medical Director of the Atlantic. He was appointed Surgeon-General in December, 1890, and served in that capacity until retired.—DR. J. C. PORTEOUS, one of the most prominent physicians and surgeons of Poughkeepsie, died suddenly at midnight on Saturday, May 11th, of valvular disease of the heart. He was surgeon of the One Hundred and Eighteenth New York Volunteers in the late war, and on account of his courageous service in his line of duty was mentioned in General Orders by General Butler. He was fifty-six years of age.

The American Neurological Association will hold its twenty-first annual meeting at Boston, on June 5, 6, and 7, 1895, at the hall of the Boston Society of Natural History.

The Canadian Medical Association will hold its annual meeting at Kingston, August 28, 29, and 30, 1895. Dr. James Stewart, of Montreal, will deliver the address in medicine, and Mr. J. H. Cameron, of Toronto, the address in surgery. It is intended to have a dermatological clinic, at which several interesting cases will be presented, and these will be discussed by prominent dermatologists. There will probably be other clinics as well. It is hoped that the first President of the Association, Sir Charles Tupper, will be present at this meeting.

Dr. F. S. Mandlebaum has been appointed pathologist to the Mount Sinai Hospital, in this city.

The Kansas Medical Society held its twenty-ninth annual meeting in Topeka on May 16th and 17th. The President of the Society was Dr. W. R. Priest, of Concordia; Vice-presidents, Drs. Gray, of Kansas City, and Tyler, of Clifton; Secretaries, Drs. Purdue, of Wichita, and Wall, of Topeka; Treasurer, Dr. Reynolds, of Horton.

The American Pediatric Society will hold its seventh annual meeting at the Virginia Hot Springs, May 27, 28, and 29, 1895, under the presidency of Dr. F. Forchheimer, of Cincinnati. A number of interesting papers are promised.

The State as a Purchaser of Secret Remedies.—A bill has been introduced into the Illinois Legislature providing for the free treatment of habitual drunkards. It provides that an habitual drunkard or any one of his relatives, when not able to pay for treatment, may petition the court for an order to have him treated at the county expense, the patient giving his written consent, and having his petition verified by three tax-payers. No special cure or institute is designated, that being left to the discretion of the court, but for whose bene-

fit the bill is intended is evident from the fact that the Keeley-cure people are the active ones in its support. Similar bills are pending in the legislatures of a number of other States.

Colleges with Four-Year Courses.—Several correspondents write to say that the Jefferson Medical College of Philadelphia was omitted from the list of four-year colleges published in our issue of April 27th. Another correspondent writes that the Medical Department of the Oregon State University, and that of the Willamette University, both in Portland, will require a four-year course, beginning with the coming fall session. This is in accordance with the resolution of the College Association, and nearly all the respectable schools in the country will do the same.

Cholera among Pilgrims.—Cholera is officially declared epidemic at Mecca, and in the villages along the Red Sea frequented by pilgrims. The pilgrimage is fortunately not as large this year as it was in 1891.

The Regulation of Prostitution.—The Anti-Vice Society has introduced into the New York Legislature a bill for the regulation of prostitution. It provides for three commissioners, having authority to district the city for the houses, and issue licenses ranging from $250 to $500. It also provides for the appointment of six physicians, drawing a fixed salary, who are to make bi-weekly examinations, and six inspectors to exercise a general supervision over these resorts. Syphilis and gonorrhœa are most dangerous when contracted innocently, and this would tend to their diminution.

Complaints Against Brooklyn Hospitals.—The Brooklyn Health Commissioner has sent a list of "rules" regarding the reception of the sick by the city hospitals. There seems to be a curious mixture of authority in Brooklyn, by virtue of which the Health Board can lay down rules for the management of hospitals. The present step has been taken because of complaints that sick and dying patients have been refused admission to hospitals: 1. All ambulance surgeons must be appointed by the Commissioner of Health, but the candidates nominated by the Hospital Superintendents will be accepted if they present satisfactory evidence of the possession of the proper qualifications for the position. 2. The hospital that is under contract with the city to treat the sick poor must maintain an emergency ward, containing not less than two beds, for the temporary reception of ambulance cases. This ward is to be used for no other purpose. 3. When an ambulance case is brought to a hospital from the latter's own district, the patient must be promptly admitted. Whether he shall be retained or not may be determined later. 4. Cases of grave injury or sickness must be admitted even when brought from another district. 5. Cases of delirium and insanity, when brought in an ambulance, must be admitted and cared for until they can be transferred to the Department of Charities. 6. Unless the free beds are all occupied, no applicant for hospital treatment is to be refused without a medical examination.

Deaths Following the Injection of Antitoxin.—A case of death following a preventive injection of antitoxin was reported by Dr. Axel Johanessen to the Medical Society of Christiania on January 9th. The patient was a boy, aged two, suffering from spastic spinal paralysis. In the Hungarian journal *Gyógyászat*, Dr. Alföldi, of Pancsova, relates the case of a girl, aged three, who received a preventive injection of 2 c.c. of Behring's serum (100 units) on January 16th. This was followed by depression and loss of appetite. On January 18th the temperature rose to over 104° F.; the child complained of pains in loins, and there was considerable albuminuria. On the 19th petechiæ appeared over the whole body, and on the 20th the child died.

A Memorial to the Late Dr. Hack Tuke.—Efforts are being made in London to raise a fund to perpetuate the memory of the late Dr. Tuke.

The Plague has reappeared at Hong-Kong.

Office Frauds and Office Thieves.—We are constantly receiving warning letters regarding office frauds and office thieves either relating the old stories of obtaining money under false pretences from the soft-hearted physician, or of stealing valuables from his office or waiting-room. If every physician would make it a rule never to give money to a stranger, and never allow him to be alone among valuables, much of the misplaced confidence business would died a natural death.

The Gross Prize.—The S. D. Gross Prize of $1,000 has been awarded to Oscar H. Allis, M.D., of Philadelphia, for his essay entitled "An Inquiry into the Difficulties Encountered in the Reduction of Dislocation of the Hip."

The Serum of the Non-immunized Horse has the same value in the treatment of diphtheria as that of the immunized animal. This is the opinion of Dr. Bertin, of Nantes, and is based upon six cases of diphtheria, of which one died.

University of California.—The California Legislature, just adjourned, has appropriated $250,000 to erect a building in San Francisco for the professional departments of the University of California. All the departments are in need of a new home, but no one of them is so badly in need of more commodious appointments as is the medical. It is to be inferred, therefore, that the medical college will get most of the money.

A Grewsome Discovery.—According to the *New York Times*, an investigation of the cause of the prevalence of contagious diseases in the schools of New York City has disclosed the fact that out of 112 school trustees 23, or a little less than twenty per cent., are undertakers; a fact which the *Times* says would be amusing were it not so tragical.—*Boston Medical and Surgical Journal.*

A New Health Resort.—The "Doctoren Collegium" of Vienna recently spent a whole evening in the praise of Ilidze, a small town of Bosnia, as a water-cure. Some of the springs have iron and sulphur, and others resemble the Marienbad and Carlsbad waters. The climate resembles that of Italy.

Leprosy.—One case of leprosy in New York and two in Brooklyn have recently been reported.

Society Reports.

American Medical Association.

Forty-sixth Annual Meeting, held in Baltimore, May 7, 8, 9, and 10, 1895.

(Continued from page 600).

FOURTH DAY, FRIDAY, MAY 10TH.

THE final session was opened by DR. N. S. DAVIS, who was called to the chair in the absence of the President. The latter entered after the minutes had been read, and presided during the rest of the meeting.

The Address on State Medicine.—DR. HENRY D. HOLTON, of Brattleboro, Vt., then delivered the address on State Medicine. He referred to the labors of Benjamin Rush in his study of epidemic diseases, a work which had brought recognition from the Russian Czar, yet was so little appreciated by the profession in America that a sum necessary for the erection of a monument to this physician, sanitarian, and statesman was yet to be contributed. The progress of sanitary science in this country was slow, and it was not until thirty years after attempts to improve the hygienic status of the poor in English towns was made that the first State Board of Health in this country was established by legislative enactment in Massachusetts. "So luminous was her example, and so active, thorough, and faithful in their teachings were the missionaries of this gospel of cleanliness and prevention that now every State in the Union, except three, have their health department established by legislative act, each of which is doing its own peculiar work, diffusing to a greater or less extent in their respective States a knowledge of personal hygiene, and exercising the powers delegated to them to prevent the spread of epidemic and contagious diseases, with the result that the citizen finds himself less liable to the contagion of pestilential disease, and with the prospect of added years to his average of life." The speaker drew special attention to the good work these State Boards have done, and commended them for their enthusiasm, their patience, and their perseverance in the varied, and often delicate, duties which have devolved upon them.

These boards have not all nor always deserved praise, for too often their members have been selected for political reasons and not by reason of their special fitness for the discharge of their peculiar duties. They have also been hampered in their work by niggardly appropriations. It is fitting that the several States should equip in the most efficient manner the militia upon which they rely for the preservation of domestic peace and for protection against possible foreign invasion, but it is painful to note how much less ready the legislators are to vote the comparatively small sums needed for the protection of the people against the invasion of the armies of micro-organisms, whose ravages are so much more destructive of human lives than could possibly be the army of a foreign foe. Vermont spends annually $20,000 more upon its militia than it does on its health department. Massachusetts, which was the pioneer among the States for sanitary science, appropriates annually $187,000 more for maintaining her military establishment than for her Board of Health; and New York, with its peculiar and special liability to invasion by all forms of pestilence, because of its large port of entry, spends nearly $800,000 more for its militia than for its health organization. The reason for this disproportion in expenditure is to be found in the state of public opinion, and an improvement can be brought about only by stirring up public opinion, by agitation as an association and as individuals.

It was not necessary, Dr. Holton said, to urge the desirability of a National Health Bureau, for this Association had more than once put itself on record as in favor of national sanitary supervision. The State boards could do good work each in its own place, but their efficiency was limited by boundary lines and by a lack of co-operation among themselves. The bill introduced into the last Congress by Senator Gray was a good measure, and ought to have become a law, but it came to an untimely death in the hands of the Committee on Epidemic Diseases. It would have been well had this bill been passed, but its failure to pass now gives opportunity for improvement by the provision for an advisory board of one member from each State and from the Medical Corps of the Army, Navy, and Marine Hospital Service. This would render it more practical and more popular. The advisory board would only meet on the call of the Secretary of Public Health to discuss and advise upon such questions as he might propose. They would be his correspondents in different parts of the country, and would be required to render such service as he might demand. In order, however, to secure the passage of any bill it will be necessary to educate the press, and through them the people and their representatives in Congress. This can best be done by the members of this Association, working individually and collectively. Good arguments for the passage of the desired measure can be gleaned from the records of the War Department, which show that during our civil war the number killed in battle, and of deaths from wounds, was 93,443, the deaths from preventable diseases was 108,666. If to this vast number who perished we add those who were disabled and broken in health by the infliction of preventable diseases that did not kill, as instance the 1,700,000 cases of diarrhœal diseases, we have the startling fact that no foe which could give us battle would decimate the active population of the country like the preventable diseases. If we desire to obtain satisfactory legislation the Association should appoint a committee composed of members who are not only familiar with the subject and its requirements, but who are able to present to the congressional committee and to other members of Congress the reason for asking, and the results reasonably to be expected from, such legislation. They would also stand as sponsors for the bill, to see that it was not unduly delayed or killed in committee. Any one conversant with the ways of legislators knows that a bill which has not active and influential sponsors is only too apt to be forgotten. Besides appointing a committee and urging its members to individual action, the Association would do well also to make an appropriation sufficient to cover all reasonable expenses in the furtherance of this measure.

Dr. Holton then outlined the work which would naturally come within the province of a National Bureau of Health. If, as Nordan claims, the number of degenerates is constantly increasing, by reason of the use of narcotics and stimulants, of tainted and adulterated food, etc., then it is time that there should be some authoritative board of the Government to inquire into the causes of this degeneracy and to devise means for their repression. Then, the safety and welfare of the people, as well as the interests of commerce, demand that quarantine be taken out of the hands of the individual States and put under the control of the Federal Government. It is not just to put the expense and responsibility of a quarantine, from which the whole country is to benefit, upon the people of one State, nor is it fair that those living in an interior State should be dependent for their protection upon the efficiency of a seaboard quarantine in the control of which they have no voice. The only remedy for such inequality is to make quarantine the business of the central government. The speaker disclaimed any intention of disparaging by these remarks the excellent work that was being done by local health boards, the State quar-

antine service, and the officers of the Marine Hospital service. He referred with especial commendation to the Canadian quarantine service under Dr. Montizambert, and said that the danger of imported disease from that source was infinitesimal.

Another function of a central health bureau would be the preparation and distribution of animal lymph for vaccination. At present the lymph is prepared by private enterprise, and there is the danger that the producers will become careless in their methods in order to avoid expense. Again, the lymph is sold through druggists, and often remains in stock for weeks, being sold finally after it has become wholly inert. It should be the duty of a National Health Bureau to produce a pure vaccine lymph under the most careful aseptic conditions, and furnish it to State Boards of Health free or at cost. The same remarks would apply to the manufacture of diphtheria antitoxin and of other protective serums that may yet be discovered.

Another subject of investigation of a National Health Bureau would be that of the effects of alcohol as a beverage. The British Medical Association, as well as the Social Science and Public Health associations, have done much to place this question upon a scientific basis: but we know that all diseases are modified by climate and environment, and it is most probable that the same would hold good in relation to the effects of alcohol. We cannot accept the conclusions of British investigators as holding good for America, and there is therefore here another field for the activity of a National Bureau. A most important matter is that of tuberculosis in cattle and its relation to the disease in man. Much work of great value has been done in this line by Law, Bryce, Ernst, Peters, and others, but much more could be done by an organized and well-appointed scientific bureau. Finally, there is the most important question of patent medicines. If the makers of these nostrums were obliged by law to deposit with the Public Health Department, under certain restrictions, as suggested by Dr. Stewart, the formulæ after which the concoctions are prepared, the evil would soon be eradicated, for it lives chiefly upon the mystery hidden behind a trade mark or taking name. The vital questions of pure water, food and drug adulteration, discovery and repression of the preventable causes of insanity and degeneration, the effects of climate upon disease, and many others, call loudly for consideration by a National Bureau of Public Health.

On motion, the thanks of the Association were tendered Dr. Holton for his address.

Dr. Osler, of Baltimore, offered a resolution urging the members to rally to the support of the "Index Medicus," the publication of which was about to cease owing to the lack of funds.

A Relief Fund.—A report was read from the committee appointed to consider the feasibility of the establishment of a benevolent fund. The successful and beneficent working of relief societies in New York and elsewhere was referred to, and it was recommended that a benevolent fund be established in the Association. On motion, the report was accepted and the committee was continued, with instructions to lay before the Association at its next meeting a feasible plan for the creation of the proposed fund.

An Anti-Greenback Resolution.—Dr. Woolsey, of California, introduced a resolution that Congress be petitioned to retire paper money of small denominations and to limit the circulating period of bills of large denominations. He believed that our paper currency was an efficient disseminator of disease, and held that it was useless to establish quarantines or sanitary cordons as long as dirty paper-money was allowed to circulate freely and to carry disease. The resolution was referred to the Section on State Medicine for consideration.

Report of the Nominating Committee.—Action was then taken on the report of the Nominating Committee (see page 595). It was moved that the report of the Committee be accepted, save those sections of it relating to the Secretary and to the place of meeting. Carried. It was then moved that the recommendation of Dr. Woodbury for Secretary be not followed, and that Dr. Atkinson, the present incumbent, be continued in office. Carried. It was then moved that the next meeting be held in Washington, in accordance with a previous resolution designating that city as the place for the celebration of the Jenner Centennial on May 14, 1896. After considerable discussion the recommendation of the Committee was sustained and Atlanta was named as the next place of meeting, Dr. W. S. Westmoreland, of Atlanta, being chosen Chairman of the Committee of Arrangements, and Dr. J. McFadden Gaston, jr., of Atlanta, Assistant Secretary.

The Office of Secretary.—A proposed amendment to the Constitution was submitted abolishing the office of Permanent Secretary and making the office an annual elective one.

Acting Assistant Surgeons.—The Association then adopted a resolution which had been submitted by the Association of Acting Assistant Surgeons, memorializing Congress to pass a bill placing those who served during the Civil War on the same plane as first lieutenants in the regular army.

Delegates to Foreign Societies.—The following were named as delegates to the meetings of Foreign Medical Societies: Drs. W. H. Daly, of Pittsburg; J. H. Ouchterlony, of Louisville, Ky.; I. N. Love, of St. Louis, Mo.; C. G. Chaddock, of St. Louis, Mo.; L. N. Montgomery, of Chicago, Ill.; A. E. Rockey, of Portland, Ore.; I. N. Quimby, of Jersey City, and H. H. Biedler, of Baltimore, Md.

Dr. Beverly Cole, the President-elect, was then introduced, and made a brief address of thanks for the honor conferred upon him.

The meeting of the Association was then adjourned.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

First Day, Tuesday, May 7th.

Mooted Points in Pelvic Surgery was the subject of the address by the Chairman, Dr. Franklin H. Martin, of Chicago, Ill. The author stated that the surgical treatment of fibroids of the uterus is always a fruitful subject of discussion. While he still uses electricity successfully in many cases of fibroids, he does not employ it in the same large proportion of cases that he formerly did. The cases in which he does the most satisfactory work with electricity now are those which the surgeons who have a wholesome regard for their statistics send to him to get rid of, or similar cases which come directly to him. They are usually large hemorrhage tumors, the subjects are anæmic, with hypertrophied hearts, diseased kidneys, skin waxy, and respiration difficult. In other words, they are the most deplorable cases that it becomes the surgeon's lot to behold. Such patients he usually treats with galvanism in strong doses, systematically and rationally applied, combined with the most appropriate tonics and alteratives.

Another class of cases in which galvanism is a justifiable means of treatment is that of the hemorrhagic variety, not of large size, the subjects of which are near the menopause. However, in the present state of pelvic and abdominal surgery, he would not voluntarily administer or recommend galvanism for fibroid tumors which are suitable for operative removal, in patients under forty years of age whose general health shows an average chance for favorable surgery. He is not willing to admit, on the other hand, that galvanism ever does harm in these cases, except-

ing that it may be the means of keeping patients away from more affective methods of surgery. It almost invariably accomplishes good, even if applied but a short time. Galvanism, excepting in fatal doses—the opinion of certain surgeons to the contrary notwithstanding—never produces peritoneal adhesions.

The second point discussed by the author was the removal of the appendages for fibroids. This operation as a remedy for fibroids of the uterus has, in his opinion, about run its course. While, since its discovery, it has served to relieve and cure many women suffering with fibroids, yet like all of the minor surgical methods for that trouble, it has the fatal element of uncertainty, which, in the light of the comparatively safe and certain hysterectomy, makes it less popular as a remedy than it was before the appearance of its more successful rival. When a laparotomy is decided upon at all for these cases, it is difficult to give one good reason why a clean sweep should not be made and hysterectomy performed. When the tumor is large and the broad ligaments consequently spread, a thorough removal of the appendages is more difficult than a hysterectomy; when the tumor is small, the patient is ordinarily in good condition, and while hysterectomy is a little more difficult than the appendage operation, no one can be justified in leaving behind a useless, diseased uterus in order to save a few minutes' time in an operation. If the appendages are diseased as the result of infection, they should certainly be carefully enucleated.

Vaginal ligation of the broad ligament was the third point discussed by the author. This operation, which was devised by him for the treatment of fibroids, is one which does not require a laparotomy. It is a minor operation in every sense of the word, excepting in its execution. It consists in ligating from the vagina more or less of the base of the broad ligaments of either side of fibroid uteri, making the ligation sufficiently deep and comprehensive to include the main channel of the uterine artery and its anomalous branches, as well as the nerve-supply which finds its way to the uterus by this route. In exceptional cases the ovarian artery may be included. The objects of this operation are to check uterine hemorrhage and cause atrophy of the uterine tumor. It may be performed with advantage in all incipient fibroids in which the operation of hysterectomy will not be accepted by the patient, while a minor operation will. It may be performed in hemorrhagic cases, where the loss of blood has reduced the patient to such a degree that it would be unsafe to submit her to hysterectomy. It may be employed when there is advanced heart or kidney disease. It should never be substituted for the more certain hysterectomy when, in the opinion of an expert, the latter can be performed with a reasonable hope of success.

As regards the treatment of the stump in abdominal hysterectomies, Dr. Martin expressed the opinion that the extra-peritoneal fixation of the pedicle as a routine method is no longer justifiable, excepting in rare cases. The objections to that method of treatment are the immovability of the pedicle, its displacement, and its exposure to internal infection. As regards abdominal drainage, the protests against this are so few and unimportant that the question of whether we should ever drain can no longer be considered as mooted. The question how and when we shall drain are points upon which there is still some discussion. He prefers the glass drainage with suction pump, which he regards as the safest and most effectual, and one which is almost invariably applicable. It accomplishes promptly and definitely the removal of all fluids from the peritoneal cavity as often as may seem necessary. For intra-abdominal sutures he considers silk as the ideal material, if it is properly sterilized beforehand and proper care is taken not to infect it afterward. Another point referred to by the author was the failure to recognize obscure kidney disease in patients before submitting them to severe operations; this has been the cause of many avoidable deaths.

Treatment of Fibroid Tumors of the Uterus—A Method of Supra-pubic Hysterectomy for Good Operators and Bad Fibroids.—Dr. Joseph Eastman, of Indianapolis, read a short paper with this title, in which he described the technique of the operation performed by him in dealing with difficult cases of uterine fibroids.

Technique of a New Method of Abdominal Hysterectomy, by Dr. Nicholas Senn, of Chicago, was the next paper read. The author stated that the chief dangers we have to guard against in performing intra-abdominal operations are hemorrhage, shock, sepsis, and injuring important neighboring organs. In all abdominal operations, the exposure of the abdominal contents to unnecessary handling and the loss of heat they sustain are most potent agents in the production of shock. Hence, in the removal of myo-fibroma of the uterus, the abdominal cavity should be exposed for as short a time as possible. With this object in view, he operates as follows: The abdomen is opened in the median line in the usual manner, and the broad ligament on each side tied; the uterus is brought well forward into the wound, and then, at a level with the section through the broad ligaments, the peritoneum is divided from one side to the other, and the flap is reflected and sewn to the parietal peritoneum; the opposite side of the uterus is then dealt with in a similar manner. It is absolutely necessary to cut only through the peritoneum to avoid the large sub-peritoneal vessels, in order to prevent hemorrhage. After closing the balance of the wound the uterus is amputated at the desired point. It is then practically an extra-peritoneal operation, as the uterus, with the tumor, is outside the peritoneum. For the purpose of preventing hemorrhage during the amputation of the uterus, he ties the uterine artery on each side, which is done by applying an indirect ligature; it is not necessary to take the time to isolate the uterine arteries. Amputation is performed by making an oblique incision, so as to make a cone of the stump of the uterus and a corresponding depression in the parts left behind. Very little hemorrhage attends this part of the operation, providing the artery on each side has been tied. After the uterus has been removed he excises the mucous membrane of the uterine canal and closes the wound at once with a row of absorbable sutures, usually chromicized catgut. For the purpose of arresting parenchymatous oozing the cut surfaces are then closely united by two additional rows of buried sutures. No elastic constriction is necessary, nothing exciting subsequent necrosis of tissue. The wound is left in a condition compatible for healing by primary union. It is packed with iodoform gauze and two secondary sutures at once inserted; twenty-four or forty-eight hours later the gauze is removed and the wound closed. If infection should occur after the operation, it is limited to the wound outside the peritoneal cavity. In thirty-five unselected cases in which Dr. Senn has performed this operation, every one of the patients recovered.

Vaginal Ligation of the Broad Ligaments for Fibroids.—Dr. C. C. Frederick, of Buffalo, read a paper on this subject. He reported three cases of fibroids in which he ligated the broad ligaments *per vaginam*, and two cases in which the ligation was performed through an abdominal incision. In the two latter cases the abdomen was opened for other causes than the treatment of the fibroids. The results in all of these cases were very satisfactory, and seem to prove that in certain instances the operation results in an absorption of the fibroid mass. The method, which was introduced by Dr. Martin, of Chicago, is not applicable to all cases, as for instance, when the vagina is very small or the tumor is large and the broad ligaments are difficult to reach. The operation is a conservative one and certainly pos-

sesses merit; it does not interfere with a more radical procedure later on, if such should be required.

Dr. Gordon, of Maine, said that two years ago he took the ground that whenever a patient comes to him complaining of symptoms which are due to the presence of a fibroid in the uterus, he unhesitatingly recommends hysterectomy. Since then he has steadily pursued the same course, and he stands to-day on precisely the same ground. He described his method of operating, and said that in every case where it is possible, he does a complete hysterectomy, taking out the cervix. Drainage is permitted through the vagina. As a rule he discards drainage through the abdominal wound. With strict asepsis and the improved technique at our command hysterectomy probably has a lower mortality rate to-day than ovariotomy.

Dr. Tuttle, of Boston, said that personally he favors total extirpation of the uterus with the cervix. By removing the latter we afford a better means of drainage through the vagina, while by leaving it there is a possible danger of subsequent malignant change occurring in its tissues.

Dr. Howard A. Kelly, of Baltimore, said he disagreed with the statement made by Dr. Gordon, and he sees no necessity for removing a fibroid tumor which is doing no harm. He does not urge the operation unless the patient is suffering in some way from the presence of the tumor; that is, unless she has pain, or hemorrhage, or pressure symptoms. Dr. Senn's method of operating he regarded as a retrograde movement in our technique. Dr. Kelly then described the technique of the operation he usually performs in the removal of fibroid growths of the uterus, which has given very good results in his hands.

Dr. Henry O. Marcy, of Boston, said he was in favor of treating the pedicle by the intra-peritoneal method. When he first suggested this some years ago, it was looked upon as an ideal but not a practical suggestion. The evolutions through which the operation of hysterectomy has recently passed is one of the marvels of modern surgery.

Dr. I. S. Stone, of Washington, said in all of the cases coming under his observation where some benefit followed the use of strong galvanic applications there was ultimately a recurrence of the symptoms and growth. The technique described by Dr. Senn he thought worthy of serious consideration. After the removal of a fibroid of large size, there is always considerable shock, and by following the plan outlined by Dr. Senn, the amount of this shock is minimized.

Dr. Massey, of Philadelphia, said that in the hands of careful men, electricity remains the most valuable agent at our command for the treatment of the hemorrhagic forms of tumor. The treatment must be persistent and long-continued. In growths of large size, the improvement following its use may be slow, and a radical surgical operation may be preferable. In one case coming under his observation, in which Dr. Martin had tied the broad ligaments through the vagina, the tumor decreased in size during the first six months and the hemorrhage was less severe, but after that there was a recurrence both of the size of the tumor and the hemorrhage. Under systematic electrical treatment the patient has since improved greatly.

Dr. George H. Noble, of Philadelphia, said he agrees with Dr. Gordon that when a fibroid gives rise to symptoms sufficiently severe to make a patient ill, it requires attention. It may not be necessary in every instance to perform hysterectomy. When they give rise to symptoms, however, it is best to remove them. During the past eighteen months he has seen five cases of fibroids which had undergone malignant degeneration.

Dr. Baldy, of Philadelphia, said that when a patient comes to him complaining of symptoms due to the presence of a fibroid, he recommends having it removed. Ligation of the uterine arteries appears to be a very plausible and attractive method of treating these cases theoretically; it simply shuts off one-half the blood-supply of the uterus, and there is no reason why a collateral circulation should not be established here, as in other regions of the body.

Dr. Dudley, of New York, said that all the various methods of operating, which were referred to by the different speakers, are applicable in proper cases. We must learn to apply the method to the case—not the case to the method. A complete and radical operation is the most brilliant and often the one most easily accomplished, but it is not always the best one for your patient.

Drs. Frederick, Senn, and Eastman then closed the discussion.

Second Day, Wednesday, May 8th.

Indications for Total Hysterectomy.—Dr. Augustus P. Clarke, of Cambridge, Mass., read a paper on this subject. The following he regarded as the principal indications for a total hysterectomy: Cases in which the uterus may be in a position opposite to that of prolapse, and in such a state of immobility, superinduced by previous inflammatory processes affecting the adnexa, and producing such adhesions of these parts, as to necessitate, for relief, operative interference. In cases of rapidly growing interstitial fibroids, or large suppurating growths developing from a broad, sessile base. In such cases the operation is indicated not only because of the hemorrhage, but also because of the pressure which may take place upon the surrounding parts, and the destruction it may produce in the vascular tissues in the abdominal and pelvic organs. If a large and rapidly growing fibroid should take on a retrograde process, either spontaneously or otherwise, the morbid growth may afford a culture-chamber into which other disease cells may find their way, and then undergo malignant degeneration. In such a condition, total hysterectomy is the only expedient that will afford a complete and permanent cure. If sarcoma is suspected in any part of the uterine system, it should be an indication for action. Total hysterectomy is absolutely necessary for uncontrollable prolapse, if anterior and posterior colporrhaphy and other plastic operations have been repeatedly tried and have failed to produce permanent relief. It is the only safe and surgical expedient to be adopted in cases of hemorrhagic polypi which present suspicious microscopical appearances after removal. It is called for in ectopic pregnancy: in such cases hemorrhage can be more safely controlled and the patient is enabled to make a more rapid recovery than by the other methods of procedure. It should be undertaken in ovarian disease, in pyosalpinx, and in old inflammation of the appendages. It should be resorted to in all suspicious disease of the adnexa, and in cases of large cysts, as well as in papillomatous developments and otherwise irremovable cysts and intraligamentous fibroids and tumors of the broad ligament.

Total Hysterectomy by a New Vagino-abdominal Method.—Dr. Albert H. Tuttle, of Cambridge, Mass., read a paper with this title. The vagino-abdominal method of hysterectomy is characterized by a division of the labor into two parts, vaginal and abdominal. The vaginal part consists of: 1. Sterilization of the cervix and vagina and their maintenance in this condition by closure of the uterine canal with a metal stem, which also serves as a guide for the limits of the cervix and for attachment of an elevating staff. 2. Abcision of the vagino-uterine attachment, dissection of the cervix from the bladder in front and the peritoneum behind, and the packing of the cavity thus formed with gauze. 3. The closure of the vaginal vault from below. (In all except cases of cervical cancer the order of items 1 and 2 are partly reversed.)

The abdominal part consists of: 1. Opening of the

abdomen by a median incision. 2. Ligaturing and section of the ovarian vessels and lateral folds of the broad ligament. 3. Incision of the peritoneal covering of the uterus in front and behind, and its separation with the bladder, to the lines of vaginal dissection. 4. Clamping of the uterine vessels, abscision and removal of the uterus. 5. Eversion of the flaps of peritoneum, with the ovarian stumps, and closure of the lower abdominal opening with concealed sutures, the serous surfaces in contact. 6. Closure aud hermetically sealing of the external abdominal wound.

The special instruments employed in the operation are the uterine stems and the elevating staff. The uterine stem is a device used to cork up the contents of the uterus; to give support and attachment to a staff used for elevating the uterus; and to serve as a guide for determining the position and limits of the cervix. It consists of a cap, to cover the cervix, and a central stem that fits into the canal, the whole being cast and turned from one piece of metal. The cap is concave on one side and convex on the other, has a groove in the edge to serve as director, and a number of T-shaped slots about the periphery for holding sutures. The central stem, two inches long, is either smooth or has a thread cut upon it, and is held in place either by the thread or by a line of sutures. Perforating the stem for the depth of an inch is a conical shaped cavity which receives the staff and holds it by a simple slip joint. The staff is a steel rod bent on the curve of a prostatic catheter, except that the point is directed a little more outward, and is made to fit the cavity of the stem. Both instruments are inserted through the vagina, but the stem is removed with the uterus from the abdominal opening.

Operation.—A short speculum is introduced into the vagina and the perineum depressed. With the help of vaginal retractors the cervix is exposed to view, and drawn as far as it will come into the introitus by means of tenacular forceps. A probe is now passed, and the direction, shape, and size of the uterine canal determined. Unless the canal is freely patent it is dilated, and treated with equal parts of tincture of iodine and carbolic acid, applied on a cotton stick. If the character of the disease is other than cervical cancer, a circular incision is made, simply cutting through vaginal structures, about the uterine neck, keeping as close to the os as possible, yet at the same time sufficiently remote to include all diseased tissues, as in the usual manner of performing vaginal hysterectomy. The uterus is now separated from its anterior and posterior attachments and coverings as freely as possible by means of the finger or handle of a scalpel, and then the cut margin of the vagina is caught with forceps and loosened sufficiently to allow it to be drawn together and sutured. A line of continuous suture is taken about one-fourth of an inch from the cut margin, and is like the ordinary purse-string suture except that the first stitch, which is placed at the back, is carried around the vaginal artery, the suture drawn so as to leave both ends of even length in the vagina, the threads crossed, and then one side of stitches taken with one end, and the other with the remaining end. In this manner the principal vessel is caught in a loop, and when the ends of the suture are drawn tight, not only is the vault of the vagina closed in, but also any tendency to hemorrhage from the vaginal artery is obviated. An uterine stem is then selected according to the length of the cervix and size of the canal; with a soft uterus and large easily dilatable cervix, one with a wide thread is used, but with a cirrhotic organ, one with a fine thread or even smooth stem is preferable. The uterine stem is inserted, and forced into place, after filling the cap with iodoform, either by simple pressure, or in case one with a thread is used by turning it up with a screw-driver, at the same time holding the cervix firmly by means of tenacula forceps fixed into the anterior and posterior lips. If the case is one of cervical cancer the stem must be inserted before any incision is made, and the contents of the uterus and infective parts tightly sealed by sewing the vagina to the edge of the metal cap with sutures taken through normal vaginal structure, and sufficiently remote from the uterus to include all diseased tissue. One then should proceed as above described for non-infective cases. It is often advisable to tie a smooth stem into the cervix with one or more sutures to prevent slipping. The staff is now inserted into the central cavity of the uterine stem and held in place by an assistant; the parts sponged clean and dry; a tampon of iodoform gauze packed into Douglas's pouch, under the peritoneum, and between the cervix and bladder; and the ends of the purse-string-like suture drawn tight and tied, closing in the vault of the vagina below the cervix, gauze, and uterine stem, except for a small opening through which the staff passes.

The patient is now placed in position for abdominal section, with means ready for obtaining the Trendelenberg posture. The usual incision is made, and of variable length, to meet the requirements of the case. The peritoneal cavity is opened at the upper angle of the wound in order that the position of the bladder can be determined before the opening is completed and injury to it avoided. The incision is carried close to the pubes to gain as much room as possible for working in the pelvis. The contents of the abdomen are carefully inspected and the method of dissection determined. If the case is a simple enlarged uterus, with appendages approximately normal, the tumor is drawn out of the wound and to one side; the fold of broad ligament, including the tube and ovary, of the other side is put on the stretch, and a row of sutures passed below the ovary from close to the side of the uterus to the free margin of the ligament, so as to include the ovarian artery. This line of sutures is inserted by means of a perineal needle; is taken like a shoemaker's stitch, but each stitch, which includes but a small amount of tissue, is drawn tight and secured by taking a turn of the loose end of the suture about the other, so as to form a series of single knots. The uterus is then pulled over to the other side, and the remaining tube, ovary, vessel, and ligament secured in the same manner. The ligaments are cut away above the ligatures, and between the points of their excision, across the uterus in front and back, about an inch above the attachment of the bladder anteriorly, and an inch above the cervix posteriorly, the peritoneal covering of the womb is incised. With the help of a scalpel handle the bladder and peritoneum are now rapidly dissected up from the uterus in front until the line of former vaginal dissection is reached; the posterior layer of peritoneum is treated in the same manner; the sides of the uterus are freed from peritoneum as much as possible; when the lateral attachments, including the uterine artery, can be easily clamped, and the organ cut away and removed. In cutting away the uterus keep as close to that organ as possible.

During the dissection an assistant holds up firmly the uterus by means of the staff, which shortens and defines the neck, and enables the operator to quickly and easily perform what is usually the most difficult part of the operation, the enucleation of the cervix. The gauze-packing acts also as a guide, and is of material assistance during this dissection. The uterine vessels are firmly ligatured with kangaroo tendon, the clamps removed, and all oozing of blood from the pedicles stopped by suturing. The anterior and posterior peritoneal flaps are brought together; the cut edges are turned in so as to bring the serous surfaces into contact, and the stumps containing the ovarian arteries are folded in at the angles so as to become extra-peritoneal, the whole being closely united by a line of blind sutures which, when drawn tight, are situated outside of the peritoneal cavity. All clots are removed by dry sponging, the abdominal wound closed layer by layer with animal ligature, and finally sealed with cotton and collodion.

Although ordinarily it is preferable to remove the ovaries should one or both be found firmly bound down by old adhesions, and in a cirrhotic condition, it is better to leave them *in situ* than to delay the operation by such time necessary for their removal. They will, as a rule, give rise to no further symptoms, as has been repeatedly demonstrated by vaginal hysterectomy, where often they must necessarily be left behind. When a large multiple fibroid mass is encountered the topography of the parts must be carefully studied, and the position of the bladder, and, if possible, the ureters, determined. If the growth forms with the uterus a single tumor, the same directions for operating as above described hold good, but where there are several distinct tumors, which are sessile in attachment and appear to have a very large pedicle, a sufficiently long cross incision is made through the peritoneal covering, and each tumor is enucleated as far as possible. By this means the pedicle will usually be found much smaller than expected, forming a part of the uterine attachment, and easily included in the clamp employed for securing the uterine vessels of the same side. Care must be taken in cutting and dissecting back the peritoneal covering not to tear or injure the ureter, the position of which cannot always be recognized. If it is determined passing over the tumor it should be dissected up and carried to one side with the overlying flap of peritoneum; but if it cannot be distinguished, any and all tissue which resembles it should be treated in the same manner, and as the clamps are applied prior to the final abscission, bear in mind the watchword of this operation, *Stick close to the uterus.*

If upon opening the abdomen, bladder, omentum, bowels, uterus, tubes, and ovaries present as a confused and conglomerated mass, firmly bound together by adhesions, the uterus can still be removed, sub-peritoneally, as follows: A point is selected on the fundus of the uterus that is not obscured by adherent viscera, and a small cross incision made through the peritoneal covering. The edges can then be picked up with forceps, the opening intelligently enlarged without injury to the adherent organs, and the peritoneum dissected from the uterus in every direction, well down on the sides, and sufficiently to admit of the easy adjustment of the clamps. The organ is cut away, the vessels secured, and the peritoneal openings closed as before, leaving the tubes and pelvis under the peritoneum to drain per vaginam. In other words, the uterus is removed by the combined method with the same consideration for its surroundings which the French operators have when they extirpate by the vaginal method.

The advantages of the vagino-abdominal method are:

Over the Vaginal Method.—1. The peritoneal cavity is completely closed, and left with no raw surface for subsequent adhesion with viscera. 2. Primary union is the rule and convalescence rapid. 3. The subsequent complication of rectocele or vesicocele is avoided. 4. The uterine vessels in all cases can be perfectly secured and there is no danger of secondary hemorrhage. 5. Abscesses of the tubes and ovaries are more completely removed.

Over the Abdominal Methods.—1. Completely subperitoneal drainage can be established. 2. The length of time which the peritoneal cavity is exposed is greatly reduced by the previous vaginal dissection, and shock is consequently diminished. (A large uterus can be removed in from twenty to thirty minutes.) 3. The limits of the cervix are closely defined and the necessary extent of the dissection readily determined. 4. The asepsis is more complete and there is less danger of subsequent infection.

Over Both.—1. The dangers of hernia are reduced; vaginal, over the vaginal method; ventral, over the extra-peritoneal treatment of a constricted stump. 2. Danger of injury to the ureters is avoided. 3. The manipulation is easier in the most difficult parts of other operations. 4. There is less danger of injury to the bladder and other viscera. 5. Hemorrhage from the vaginal artery is avoided. 6. The operation is practically bloodless. 7. It offers a means for removing large uterine tumors with extensive adhesions, which could only be done with great difficulty or not at all by the other methods. 8. Its greater perfection of the principles of modern aseptic surgery.

Vaginal Hysterectomy for Pelvic Suppurative Diseases and Results.—Dr. I. S. Stone, of Washington, D. C., presented a communication in which he stated that since we have found that the uterus may be removed by the vagina with less shock to the patient than by the abdominal method, we may consider the operation of vaginal hysterectomy as applicable to other diseased conditions than cancer, for which it was first designed. In common with other operators, it is the writer's practice to remove the uterus and the adnexa by the vaginal route for the following conditions: 1. Where operations had been done for salpingitis or purulent collections within the pelvis, leaving extensive adhesions and even an irritative endometritis and vaginitis. 2. In cases where a partial hysterectomy had been done by the supra-vaginal method, leaving a sinus or fecal fistula. 3. In sepsis of the uterus, septic metritis, as after abortion, etc. 4. In purulent collections outside the uterus, pelvic abscess, hyosalpinx, or ovarian abscess.

Vaginal Hysterectomy.—Dr. Edward Garceau, of Boston, Mass., read a short paper on this subject, and showed a number of drawings to illustrate the technique of his operation.

Hysterectomy for Suppurative Disease of the Pelvic Organs.—Dr. J. M. Baldy, of Philadelphia, read the paper. He stated that when in October, 1893, he read a paper on this subject before the Philadelphia Obstetrical Society, and for the first time proposed this procedure as a matter of election, his remarks met with a strong protest and almost universal disapproval To-day the operation is established on a sure and firm basis, and many women who were before doomed to a partial recovery are now blessed with a complete return to health. There is no one who has practised gynecological surgery to even a limited extent but knows that patients suffering from chronic pelvic inflammatory disease are not always cured of their symptoms by the removal of the tubes and ovaries alone. As to whether or not patients are cured after hysterectomy, when double ovariotomy has failed, experience must decide. Six patients are at present under his observation who have been rescued from chronic invalidism by a hysterectomy subsequent to a double salpingo-oöphorectomy.

As regards the mortality following hysterectomy in these cases, of 34 thus far operated on by him, not a single one died. In addition to his own cases, 189 have been reported by five other operators, making a grand total of 223 cases, and a mortality-rate of 2.7 per cent.

It must not be understood that the removal of the uterus, together with the Fallopian tubes and ovaries, is recommended in all cases of pelvic inflammatory disease. In many cases the uterus has succeeded in throwing off the original infection and is comparatively healthy, if not entirely so. Under such circumstances hysterectomy is not indicated. But where an abdominal section has been performed for the removal of the uterine appendages, and the womb is found enlarged and diseased, especially if it has been surrounded by extensive adhesions, the destruction of which leaves large areas of denuded peritoneum, hysterectomy should be the operation of choice.

The Treatment of the Stump in Oöphoro-salpingotomy—A New Method.—Dr. L. H. Dunning, of Indianapolis, stated that there are several serious objections to the method now almost universally employed of treating the pedicle and stump in the operation for the removal of the Fallopian tubes and ovaries. For

some years past he has been striving to devise some method that is safe and free from the objection of the *en masse* method. He does not claim to have found a perfectly safe method, and one that is applicable to all cases in which it is necessary to remove the tubes and ovaries; he does claim, however, that when the method he proposes is applicable, it is far superior in its results to the older procedure. His plan is as follows:

After proceeding with the operation in the usual manner until the adhesions are so far broken up as to permit of the tubes and ovaries being brought into view, the uterus is lifted up toward the abdominal incision by the finger of an assistant making pressure through the vagina. A provisional ligature is thrown around the Fallopian tube close to the uterus. With scissors the tube is cut off beyond this ligature, the severed end is seized by the thumb and finger of the left hand and gentle traction is made upon it, while with a knife or blunt-pointed scissors the tube is cut away by severing the meso-salpinx close to the tube. After its removal one or two small arteries will be found spurting; these can be caught and tied with fine catgut. The ovary may now be taken in hand and its attachment to the broad ligament severed close to the organ. Then take a straight needle, threaded with fine catgut, and beginning at the outer margin of the incised surface, with a running stitch close in all of the raw surfaces, employing the Lembert suture. This completed, tunnel out the uterine end of the Fallopian tube and close the raw surface with fine catgut. Then remove the provisional ligature. Proceed with the opposite side in a similar manner. A dexterous and rapid operator will require from five to eight minutes to accomplish this work on both sides. It takes a little more time than the *en masse* method, and this may be an objection to it in rare instances where rapidity of work is demanded on account of the critical condition of the patient. The method is not easily applied when for any reason the uterus cannot be brought up near the abdominal incision. Dr. Dunning said he has now employed this method in nine cases with great satisfaction in each instance.

The Etiology and Treatment of Inflammations of the Uterine Appendages.—Dr. Augustin H. Goelet, of New York, read a paper on this subject. He stated that for some years past the surgical tendency of the gynecologist has completely overshadowed the rational treatment of diseases of the uterine appendages, and may be regarded as a confession of inability to cure; for no more can it be claimed that the ablation of organs so important to the female economy is a cure of the morbid process than amputation of a limb is a cure of the injured or diseased member. Anyone who has had experience with diseased appendages will admit that it is much easier to remove them than to attempt to bring about resolution of the morbid process and save them. The contention is not that these inflammations of the tubes and ovaries can always be cured, but that it is frequently possible, and that unless immediate operative interference is demanded, the patient should be given the chance and the attempt should be made before submitting her to a radical operation.

Clinically, inflammations of the uterine appendages may be divided into salpingitis and ovaritis, and it is quite impossible to institute rational and successful treatment without first ascertaining both the direct and the indirect cause of the morbid process. Chronic ovaritis may exist as a condition of atrophy, hyperplasia, or cystic degeneration, but the term is most frequently applied to a condition of passive hyperæmia, which, if unrelieved, may result in hyperplasia. Probably one of the most frequent causes of chronic ovaritis is laceration of the cervix during parturition, with subsequent infection through the medium of the lymphatics. It may be the result of an endometritis or growths within the uterus, especially if located in the cervical canal, such as polypi. Fissures of the anus, ulceration of the rectum, and chronic proctitis are also frequent causes of ovarian irritation and hyperæmia.

When salpingitis is found to be associated with a severe type of chronic endometritis with an hypertrophied or granular condition of the mucous membrane, the first step in the treatment should be dilatation of the canal, thorough curettage of both the body and the cervix, followed by packing with iodoform gauze. This should only be regarded as a preliminary step in the treatment, for it is necessary to maintain free drainage from the uterine cavity and tubes, remove all sources of irritation and institute measures which will promote absorption of surrounding exudates and relieve the engorgement of the pelvic vessels. To accomplish the first end, a patulous condition of the cervical canal must be preserved, and the uterine cavity must be kept free from all *débris*, such as small clots and particles of mucus. This is accomplished by the occasional introduction of a small (clinical) irrigator and washing out the cavity with a one per cent. solution of lysol or Thiersch's solution. The absorption of exudates and the restoration of the normal circulation of the pelvis is accomplished by the persistent application of the faradic current of high tension, made sufficiently stimulating to suit each individual case. This not only quickens the capillary circulation and hastens absorption, but by stimulating contraction of the tube-walls and the uterus it favors evacuation of the tubes into the uterus and empties the uterus as well. When salpingitis is associated with simple catarrhal endometritis curettage is not needed. The treatment of ovaritis consists in removing the source of irritation or the cause, when ascertainable, as far as possible.

In connection with his paper, Dr. Goelet exhibited a metal double-current irrigator which he has found very serviceable in washing out the uterus. He also reported a number of cases illustrative of his method of treatment.

Dr. Charles P. Noble, of Philadelphia, said the method of treating the stump advocated by Dr. Dunning was practically the same as that employed by Dr. Pratt, of Chicago. The only difference he saw was that the latter did not put in a provisional suture. Dr. Goelet's paper was interesting, but did not contain anything particularly new on the subject.

Dr. M. Price, of Philadelphia, said he wished to criticise the tendency constantly manifested to devise new methods. This is not necessary, because the rules laid down by the older surgeons, such as Tait and Keith, answer every purpose. The speaker said he agreed with the statement made by Dr. Goelet that many patients with ovaritis and salpingitis are being operated on unnecessarily. During the past year he has turned away many women, telling them that there was nothing the matter with their tubes or ovaries, and yet nearly all of them succeeded in finding another surgeon to remove their appendages. In cases where actual tubal or ovarian disease exists, he regards simple curettage and drainage of the uterus as futile. In many of these cases the cervical end of the tube is entirely obliterated by the inflammatory condition.

Drs. Dunning and Goelet then closed the discussion.

Hysterectomy for Puerperal Infection.—Dr. Reuben Peterson, of Grand Rapids, read a paper on this subject, of which the following is a summary: 1. Puerperal sepsis is still a common disease, although in the hospitals the mortality from this source is practically *nil*. 2. There are two forms of puerperal endometritis, (*a*) putrid; (*b*) septic. 3. In the septic form there may or may not be present a granulating zone acting as a barrier to the further penetration of the germs. 4. Putrefactive germs may be absent: hence fetid lochia may also be absent. 5. Putrid endometritis signifies necrosis of the lining membrane of the uterus and the presence of decomposed material. 6. This variety is prone to develop toxins, the absorption of which gives rise to sap-

ræmia. 7. Clinically, cases of puerperal septicæmia may be separated into two large divisions, (*a*) where general infection predominates; (*b*) where localized inflammatory deposits are present, the general infection being secondary and less important. 8. The area of septic inflammation may be in the adnexa, pelvis, cellular tissue, or peritoneum. 9. This class of cases presents the most favorable field for operative procedures. 10. It is almost impossible to make a differential diagnosis between those cases of septic infection having a granulating zone in the uterine tissue and those where it is absent. 11. These cases should be curetted with a dull instrument and packed with gauze. 12. If there is no improvement in the symptoms within twelve or eighteen hours, the source of the infection, namely, the uterus, should be removed. 13. Hysterectomy should not be condemned because of its failure when performed too late. 14. If this operation be done early enough, it will be the means of saving a number of lives.

Cœliotomy for Puerperal Septicæmia and for Puerperal Inflammatory Conditions.—Dr. Charles P. Noble, of Philadelphia, Pa., said that the present status of the subject of cœliotomy for puerperal septicæmia and puerperal inflammatory conditions may be summed up as follows: These cases may be divided into two classes: 1. Those having morbid conditions in the pelvis antedating labor, such as tumors, pus-tubes, or other septic accumulations, the bruising or rupture of which during labor leads to peritonitis or septicæmia. Prompt operation in these cases has given good results. 2. Those having normal pelvic structures at the onset of labor. The infective process may spread through the lymphatics to the peritoneum, and give rise to peritonitis, cellulitis, and septicæmia. It may spread by way of the Fallopian tubes to the peritoneum, or it may be limited to the utero-vaginal canal. Cœliotomy is not indicated in lymphoid peritonitis, as the morbid process is too wide-spread to be reached by operation. Cœliotomy is very fatal in cases of general puerperal peritonitis. The only ground for advising the operation with such a diagnosis is the possibility that the diagnosis may be erroneous. The prognosis is best when cœliotomy is done for localized peritonitis, when the process has become more circumscribed, and the element of sepsis eliminated; in other words, when the case has resolved itself into one of pyosalpinx, abscess of the ovary, or of pelvic abscess of puerperal origin. The prognosis is good when cases of localized peritonitis are operated on promptly; that is, within two or three days of the beginning of the attack, or at about the end of the first week of the puerperium. Hysterectomy is indicated for those cases in which the infection is limited to the utero-vaginal canal, when in spite of thorough curettement of the uterus, together with copious irrigation and the employment of proper systemic treatment the infectious process increases in severity. In dealing with the lesions of puerperal septicæmia by operation, cœliotomy affords an opportunity for satisfactory diagnosis and adequate treatment. The organs involved may be palpated and inspected, and when necessary the operation may be followed by irrigation and satisfactory drainage. The vaginal route is indicated when there are large pus accumulations which are found late in the puerperium.

Dr. A. Lapthorn Smith, of Montreal, said that when we have to deal with a case of puerperal fever which in spite of careful curetting and irrigation continues to grow worse, an operation should be resorted to. He was among the first to open the abdomen for this condition. In such a case the infective process has invaded the walls of the uterus itself and the lymphatics that run along its side, and the only rational thing to do is to open the abdomen and remove the uterus. He is strongly in favor of the abdominal method, in preference to the vaginal, as it gives us a better opportunity to completely eliminate the source of the infection.

Dr. Henry Newman, of Chicago, expressed the opinion that by merely curetting the uterine cavity we accomplish very little in these cases. It is his practice to supplement the curetting by swabbing out the uterus with a ninety-five per cent. solution of carbolic acid.

Dr. Dunning reported two cases coming under his observation in which the presence of pus in the pelvic cavity antedating delivery gave rise to puerperal septicæmia.

Dr. J. H. Carson, of Detroit, said that in certain cases, where the puerperal symptoms are due to the presence of small pieces of placenta or membranes in the uterus, curetting and swabbing with strong carbolic acid is often all that is necessary. He is not in favor of packing the cavity with gauze after curetting, believing that freer drainage will take place without it. There are other cases of puerperal septicæmia, coming on late, that is, about the ninth or tenth day after delivery, which are the result of some peculiar kind of infection and often end fatally.

Dr. W. H. Humiston, of Cleveland, referred to two cases of puerperal septicæmia coming under his observation during the past year. In both he advised hysterectomy, and in both cases the operation was refused. One of the patients died after a prolonged illness while the other recovered.

Dr. John M. Duff, of Pittsburg, said that when improvement does not occur in these cases after the usual plan of treatment has been faithfully carried out, it is our duty to operate.

Dr. L. S. McMurtry, of Louisville, said he thought it would be a great misfortune to have the statement go out from this meeting that in every case of puerperal fever which does not yield to ordinary treatment a hysterectomy is demanded. Puerperal fever is very common, and the majority of the cases recover under an expectant plan of treatment. In his opinion hysterectomy should only be resorted to on the same principles that it is done in other conditions. When there are some demonstrable lesions in the pelvis, then it is proper to resort to an operation.

Dr. M. Price said he never employs the curette, the use of which he regards as very injurious in any form of puerperal fever. Tamponing the uterus with gauze should also be avoided. As regards the performance of hysterectomy in puerperal septicæmia, it should be considered nothing less than a criminal procedure. If this operation is done in such a case and recovery occurs, it is the result of a happy accident and not the surgeon's skill.

The discussion was continued by Drs. Baldy and J. C. Dacosta, of Philadelphia, and Dr. Davis, of Birmingham, Ala., and then closed by Drs. Noble and Peterson.

SECTION ON DISEASES OF CHILDREN.

Second Day, Wednesday, May 8th.

Antitoxin in Diphtheria.—Dr. Louis Fischer, of New York, read a paper giving a summary of his clinical experience in hospital and private practice with diphtheria antitoxin. The percentage of mortality estimated previously to using antitoxin was probably fifty-five per cent. In April, the speaker reported over two hundred cases with an average mortality of about fifteen per cent. In cases complicated with other diseases, such as measles and scarlet fever, the antitoxin does not produce such good results. The use of an inferior preparation, the author thinks, is confusing results and adversely prejudicial to the treatment. The preparation of German antitoxin is under State control, and this assures satisfactory preparations and unvarying strength.

Cases were read to illustrate the effects of the antitoxin and charts of the temperature record, etc. A new syringe, made by Codman & Shurtleff, was exhibited.

One severe case of laryngeal stenosis requiring intubation, considered hopeless, was remarkably relieved and got well promptly by use, after intubation, of antitoxin. It was one of those very malignant cases; no one who saw it had any expectation of its recovery. Remarkably good results have been observed by the author, as by reporters abroad, of the combination of intubation and antitoxin.

The author claims that his results have been five hundred per cent. better with antitoxin than previously by any treatment. The Berlin experience of reduction of mortality by this treatment from forty to twelve per cent., and its sudden return to the former figures or discontinuance of it, was referred to as important. The reader cannot attribute results to any other cause than the antitoxin. He would not dispense with its use any more than with mercury in syphilis. He confines himself to using the German preparation, Behring's.

Clinical Experience in the Treatment of Diphtheria with Antitoxin.—Dr. A. Campbell White, of New York, followed with a paper on this subject. We have had experience in this country of about a year; but only six months of reliable experience, because of the difficulty of obtaining good preparations. Abroad the experience has been larger. We have been only copying them. We ought now to be in a position to declare whether antitoxin is really beneficial or not. Laboratory testimony of antitoxin in animals in curing diphtheria is all favorable. Clinical study only corroborates the laboratory experience. Some reporters declare it of no benefit, others can attribute only to it the good results obtained. The explanation is in the different conditions, complication of cases, and inferior preparations of antitoxin. These factors have vitiated results in the case of those who have obtained no good. The reader reaffirms former published statements that he has no doubt of the curative and specific action of antitoxin in diphtheria.

Experiences were then related *in extenso*. Mild cases will get well, of course, and it is difficult in these cases to estimate the effect of antitoxin, but it is in the malignant or severe cases where it must be tested to prove its real worth or uselessness. The most important effect is shown in the power of the remedy to abort or check the development of the disease. Used early, the author had not failed to observe marked effects. In the cases where there is extensive glandular enlargement and pain in deglutition, marked effects for relief in pain and swelling follow more quickly than by other remedies.

Its Effects on Systemic Symptoms, Temperature, and Pulse.—This last symptom is so varying in most cases of diphtheria that it is difficult to estimate the effect; on the pulse it may be easier to be seen. Paralyses seem to be diminished in severity and frequency. On the kidneys the effects are, if anything, to lessen this complication. The symptoms do not change immediately, but after about twelve hours they often occur suddenly. Dr. Winter's opinion that the antitoxin produced no good effects is erroneous; his observations are inadequate. The reader has never seen any dangerous effects ascribable to the use of antitoxin.

Conclusion: Antitoxin is a specific and reliable cure for diphtheria, and if a properly prepared serum is used with discretion, it is free from any danger[illegible]s effects. It is important to have a good syringe, properly disinfected. Several syringes were displayed by the reader, one of his own adaptation made by Ford.

Lacunar Diphtheria of the Tonsil.—Dr. Henry Koplik, of New York, read a paper on this subject. He referred to Trousseau's observation of certain forms of tonsillitis followed by paralysis, in which there was no membrane, and regarded as non-diphtheritic. The disagreement between Fränkel and Jacobi on the subject was cited, Jacobi taking the ground that diphtheria may be present without any membrane, while Fränkel denied this. Observations were mentioned by the author of cases in which contagiousness was proved where there was no membrane, giving rise in some cases to malignant diphtheria in other members of the same family. These observations have been published.

The first class of these cases clinically cannot be distinguished from simple follicular tonsillitis; in another class there is more depression. There may be great depression, septic symptoms, perhaps low temperature—in fine, the symptoms of genuine diphtheria. Bacilli found in these two classes of cases are virulent.

What shall One do with these Cases?—A case was cited in which diphtheria developed in a freshly cut surface of the stump after tonsillotomy. From this the author drew the conclusion that the follicles of the tonsil afforded a lodging-place for the bacillus, which developed on the freshly cut surface. It is time to drop the theory that there is no diphtheria present without membrane. Cases of tonsillitis should be isolated and watched.

False Croup.—Dr. Starling Loving, of Columbus, O., read a paper with this title. The reader began by referring to our frequent embarrassment before cases, as to whether we had true croup or false croup, by which he referred to catarrhal and spasmodic croup. He acknowledged his own mistakes in the matter. The false croup was always recovered from, and this was favorable to statistics of purported true croup. False croup may prevail to a considerable extent at a given time, but is not truly contagious or communicable. True croup is rare, false croup very common.

False croup, like bronchitis, is often preceded by coryza. There is catarrh of the pharynx, larynx, and trachea. True croup is also preceded by catarrhal symptoms, but of more severe character, with bronchitis, frequently swelling and soreness of cervical and submaxillary glands. Pharyngeal diphtheria may be present, when the diagnosis is rendered much more probable. The dyspnœa in false croup is greatest during the early part of the attack, during the first twenty-four hours. This is more or less true of other symptoms. After this the difficult breathing is usually relieved. In true croup there is progression of severity of symptoms until the end, or until separation of the membrane. There is frequently chill at the beginning. The heart and pulse grows weaker with the progress of the disease. There is fever continued throughout; head symptoms may arise. Appetite is absent. Emetics do not produce permanent good, in fact harm in the depression following them. While in false croup vomiting gives marked relief, which is often permanent as to the dyspnœa. In false croup the voice may be suppressed to a whisper. Symptoms develop rapidly in false croup; in diphtheria of the larynx they may occur rather quickly, but not as a rule. Examination of the throat, if the membrane can be seen, often a difficult thing, of course settles the diagnosis.

If death occurs in false croup it is rare; probably in such cases autopsy would show true croup. False croup is apt to recur in the same patient—one attack induces another. As to this feature we are not altogether decided in the case of diphtheritic croup. The bacillus cannot always be found when present, but when it can be is conclusive.

Dr. J. P. Crozier Griffith, of Philadelphia, was impressed by the fact that the Philadelphia physicians do not see so many cases of diphtheria as are seen in New York—in fact only, as a rule, sporadic cases. The speaker was somewhat sceptical regarding the antitoxin, on account of failures of other vaunted remedies, but he had got now where he should want to use it were he attacked by diphtheria. In lacunar tonsillitis experience had taught him great caution, and to isolate his cases. No doubt some apparently simple cases proved to be diphtheria.

Dr. Welch felt that he had not much to say. As to antitoxin in diphtheria he had had some little

experience—something like a hundred cases. The speaker expressed appreciation of the desirability of such a remedy, but he acknowledged his disappointment in the results of the use of antitoxin as far as his own observations go. Other remedies have given as good results in his hands. However, he would not condemn it on his present experiences, but wait for more. Behring's (No. 2) had been mostly used. The results in the hundred cases give a mortality of about twenty-five per cent., while previous experience gave about twenty-eight per cent. In the former the hopeless cases were excluded from the statistics. Dr. Welch referred to his frequent experience of cases in the same family, illustrating diphtheria confined to particular regions in one, the nose perhaps, and another the pharynx or the larynx.

Dr. J. O. Larrabee, of Louisville, Ky., said that when reporters gave such results as the last speaker he had grave doubts as to their absolute reliability in some way. This applied to some extravagant statements of a speaker regarding his successes with the use of antitoxin in diphtheria. He referred to Jenner's discovery, "who shut the doors of death on small-pox." The discovery proved itself by this and needed nothing more. The same course will prove the crucial test in regard to antitoxin. It will stand or fall on it. We now believe it will stand, but it is not yet time for extravagant enthusiasm. The speaker spoke of a form of tonsillitis arising from drain- or sewer-poisoning, which is communicable, seeming to be a specific disease, but not true diphtheria.

In regard to the term false croup, he wished to express his hope that the time of negative names for disease, like false, would come to an end some time. It was not creditable to scientific medicine to continue to use such terms to describe diseases; names ought to be affirmative and inclusive, not negative and exclusive; truly descriptive of the entity, if possible. The speaker emphasized the point claimed by some that the great difference in results reported from the use of antitoxin was very largely due to the use of different preparations of the serum. The bad results were due to bad serum. He referred to the professional prejudice at the time of Jenner.

Dr. Ingalls, of Chicago, remarked that we were probably on the right track with antitoxin. Observations reported are often worthless because of doubtful diagnosis. There was no use of such report scientifically unless there was bacteriological proof of the disease furnished by reliable bacteriologists.

Many of the cases reported lack proof of presence of the specific germ of the disease. This vitiates the statistics, to begin with. Again, the rate of death varies from ten to seventy per cent. in the same epidemic at different periods, sometimes under the old treatment. We may be in the right way, but at present we are not absolutely sure. But we are sure enough to warrant every physician in not neglecting to use the remedy.

Dr. Young, of Newark, regards antitoxin as a baby in long clothes, which he has great hopes to see grow to vigorous adult life. Results have been good in his practice without it, largely by the use of pilocarpin.

One speaker, claiming large experience with diphtheria and lacunar tonsillitis, regards the latter as always suspicious and takes precautions as in cases of undoubted diphtheria. Reported a case, regarded as hopeless, in which antitoxin, two strong doses, was followed by recovery. This case made a great impression on him, favorable to the remedy.

Dr. Fischer, in rebuttal, spoke of what Dr. Ingalls had said. He objected to the term experimentation as applied to antitoxin now. There are two rival factions in Germany, one is Behring's, the other Aronson's. The different preparations of Behring should be carefully distinguished, and these from Aronson's. In using antitoxin no cases, however bad, unless actually moribund, should be excluded from treatment, nor their results from statistics, as had been done in Dr. Welch's cases. He would like to have Dr. Welch allow him to send him some of the antitoxin which he employs, and try it without prejudice. He had confidence that Dr. Welch would, after using it, change his opinion. All this scepticism has come since so many new preparations have come into use, and is due to the inferiority of many of these. Solid antitoxin has been produced in Germany, but does not keep so well as the fluid.

Dr. White, in rebuttal, remarked that he believed we put too much importance in statistics. Actual experience in cases was absolutely convincing to him, without any statistics, after a large experience with and without its use. In answer to Dr. Ingalls as to the variation of mortality in the same epidemic, it should be remembered that this had been answered by actual experience in the discontinuance of the remedy, and then resuming it, in the same institutions in Germany and France, where it was found that the mortality increased with such discontinuance, and again would improve with its resumption. He thinks cases develop from simple to diphtheritic inflammation by the presence of Klebs-Loeffler bacillus in the throat, which have not developed until after the ground had been prepared by the simple inflammation. This would, perhaps, account for many cases of follicular tonsillitis, which prove, on bacteriological examination, to be diphtheria.

Dr. Loving, in rebuttal said, he believed he had seen membranous croup not caused by diphtheritic infection—cases which are not communicable—do not contain the specific germ. He believes lacunar diphtheria of the tonsil extremely rare. Follicular tonsillitis is mostly due to suppurative germs, not to the Klebs-Loeffler bacillus. He deprecated that he could not make names for disease, but must use those already applied by the profession. He was aware that false croup was a bad term.

Election of Officers.—The following officers were elected for the ensuing year: *Chairman*, Dr. A. C. Cotton, of Chicago; *Secretary*, Dr. J. A. Work, of Elkhart, Ind.; *Executive Committee*, Dr. C. G. Jennings, of Detroit; Dr. W. S. Christopher, of Chicago, and Dr. Edward H. Small, of Pittsburg, Pa.

(To be continued.)

ASSOCIATION ITEMS.

Receptions.—On Tuesday evening receptions were held at the residences of Dr. Chisolm, Johnson, and Kelly; on Wednesday evening at the Johns Hopkins Hospital; on Thursday evening at the Music Hall.

The First Annual Meeting of the Association was held in Baltimore, on May 2, 1848; the first small-pox hospital in the United States was established there by Dr. Henry Stevenson in 1769; the first dental college was organized there in 1839.

The Judicial Council might well, from the character and tone of its decisions, be called the Judicious Council.

The Faculty of the Woman's Medical College gave a reception on Wednesday evening to the wives and daughters of the visiting physicians and to the women members of the Association, at the college building, corner of Hoffman and McCulloh Streets.

The Hymn to Hygeia, composed by Dr. John C. Hemmeter, was sung at the reception on Thursday evening in the Music Hall.

Association of Acting Assistant Surgeons.—At a meeting of this association held on Wednesday, a resolution was adopted to memorialize Congress to commission acting assistant surgeons of the army to the rank

and pay of lieutenants. The following are the officers of the association: *President*, D. S. Lamb, of Washington; *Vice-Presidents*, J. L. Ord, of California, A. L. Comfort, of Wisconsin, and John P. Pratt, of Massachusetts; *Recorder*, W. T. Parker, of Massachusetts; *Register*, J. S. McLain, of Washington, D. C.; *Council*, H. M. Deebles, Charles W. Gumbes, Samuel C. Benedict, W. C. Dixon, H. R. Porter, G. L. M. Gilliculdy, W. J. Hoffman and A. F. Paftee.

The Flint Club entertained a number of the visiting physicians at a supper on Wednesday evening.

Officers of Sections.—The following were elected: *Neurology*—Chairman, Dr. T. D. Crothers, of Hartford, Conn.; secretary, Dr. William J. Herdman, of Milwaukee, Wis. *Materia Medica*—Chairman, Dr. F. E. Stewart, of New York; secretary, Dr. W. B. Hill, of Milwaukee, Wis. *Ophthalmology*—Chairman, Dr. Lucien Howe, of Buffalo, N. Y.; secretary, Dr. Frank Allport, of Minneapolis, Minn. *Practice of Medicine*—Chairman, Dr. William E. Quine, of Chicago, Ill.; secretary, Dr. DeLancey Rochester, of Buffalo, N. Y. *Dental and Oral Surgery*—Chairman, Dr. R. R. Andrews, of Massachusetts; secretary, Dr. Eugene Talbot, of Chicago, Ill. *State Medicine*—Chairman, Dr. Charles H. Shepard, of Brooklyn, N. Y.; secretary, Dr. Albert L. Gihon, U. S. Navy, Washington, D.C. *Dermatology*—Chairman, Dr. L. Duncan Bulkley, of New York City; secretary, Dr. T. C. Gilchrist, of Baltimore, Md. *Laryngology and Otology*—Chairman, Dr. G. V. Woolen, of Indianapolis, Ind.; secretary, Dr. M. R. Ward, of Pittsburg, Pa. *Obstetrics*—Chairman, Dr. Joseph Taber Johnston, of Washington, D.C.; secretary, Dr. Reuben Peterson, of Grand Rapids, Mich. *Surgery*—Chairman, Dr. C. A. Wheaton, of St. Paul, Minn.; secretary, Dr. W. L. Estes, of South Bethlehem, Pa. *Diseases of Children*—Chairman, Dr. A. C. Cotton, of Chicago, Ill.; secretary, Dr. J. A. Work, of Elkhart, Ind.

American Medical College Association.—At the last meeting of this Association the constitution was so amended that all candidates for the degree of M.D. in 1899, or thereafter, shall have pursued the study of medicine for a period of four years and attended at least four courses of lectures of not less than six months' duration each. This includes the students entering the institutions in the fall of 1895. To this plan some of the colleges were opposed; they asked for an extension of time when the four years' course should go into effect. A letter was read from Dr. Thomas Opie, Dean of the College of Physicians and Surgeons, of Baltimore, proposing that the time for the four years' course to go into effect be changed to the students entering the schools in 1900, or an extension of the time to five years. The convention decided by 29 to 5 that the four-years' course shall go into effect with the students entering in 1895. The Association elected the following officers: *President*, Dr. William Osler, of Baltimore; *Vice-Presidents*, Drs. J. M. Bodine, of Louisville, and D. W. Graham, of Chicago; *Secretary and Treasurer*, Dr. Bayard Holmes, of Chicago.

Fête Champêtre.—A lawn party was given at the Sheppard Asylum on Thursday afternoon. The day was fair, and most of the visiting ladies were present.

Club Privileges.—The Athenæum, University, and Catholic Clubs offered the privileges of their house to the members of the Association, and to the ladies the privileges of the rooms of the Arundel Club were extended.

The Metric System has been officially adopted by the Association, and all members are requested to employ this system in papers presented at future meetings.

The Weather during the week was warm and humid, with occasional showers.

An Excursion to Gettysburg was made by special train on Friday, nearly two hundred of the members and their ladies taking this opportunity to visit the historic grounds.

Hospitals.—On Wednesday a number of the hospitals of the city were inspected by the members of the Association. The hospitals thrown open were the Baltimore City Hospital and College of Physicians and Surgeons, Baltimore Medical College and Maryland General Hospital, Baltimore University Hospital and Medical School, Garrett Free Hospital for Children, Hebrew Hospital, Hospital for Women of Maryland, Hospital of Good Samaritan, Johns Hopkins Hospital, Maryland University Hospital and Medical School, Presbyterian Eye and Ear Hospital, Sheppard Asylum, St. Agnes's Hospital, St. Joseph's Hospital, United States Marine Hospital.

The Association of American Medical Editors elected the following officers: *President*, Dr. George M. Gould, of Philadelphia; *Treasurer*, Dr. Ohman Dumesnil, of St. Louis; and *Secretary*, Dr. H. B. Ellis, of Los Angeles, Cal.

State Examining Boards.—A conference of officers of a large number of the State Medical Examining Boards was held on Thursday, with Dr. William E. Quine, of Chicago, in the chair. The adoption of a constitution and by-laws for the government of the organization was discussed, and a committee was appointed to draft the same. The following officers for the ensuing year were elected: *President*, Dr. W. W. Potter, of Buffalo; *Vice-President*, Dr. J. M. Hayes, of Greensboro, N. C.; *Secretary*, Dr. B. N. Griffith, of Springfield, Ill. The selection of the time and place of the next meeting was left to the president and secretary. The object of the Association is to establish a uniform standard of requirements for all the medical colleges and examining boards in the country.

The Jenner Centennial.—Dr. J. M. Toner, of Washington, chairman of the committee to provide for the celebration in Washington, May 14, 1896, of the anniversary of Jenner's discovery of vaccination, sent a letter requesting to be relieved of his duties by reason of ill-health.

The Section Meetings and general sessions were all held in one building, the Music Hall. This was a great convenience for those who desired to attend the general sessions as well as the meeting of their own section. The acoustic properties of the main auditorium, where the general sessions and the meetings of the gynecological section were held, were very bad, and even the best speakers could not be heard at a little distance from the platform.

Medical Temperance Association.—The annual meeting of this society was held on Thursday. Dr. N. S. Davis read a paper entitled: "Does Alcohol ever Act as a Food or as a Generator of any Natural Force in the Living Body?" His answer to this question was in the negative. He thought that alcohol might possibly retard wasting of the tissues, but this is not equivalent to the building up of tissues. The following officers were elected to serve during the ensuing year: *President*, Dr. N. S. Davis, of Chicago; *Vice-Presidents*, Dr. J. M. Quimby, of Jersey City, Dr. J. B. Whiting, of Wisconsin, Dr. T. E. Yoakum, of Louisiana, and Dr. J. Taft, of Cincinnati; *Secretary*, Dr. T. D. Crothers, of Hartford, Conn.; *Treasurer*, Dr. G. W. Webster, of Chicago, and *Corresponding Secretary*, Dr. J. H. Kellogg, of Battle Creek, Mich.

The Vice-Presidents.—The wires made havoc of the residences of the vice-presidents elect in the list which was telegraphed from Baltimore and printed on page 595. Dr. Clark, the third vice-president, is from Massachusetts, and the fourth vice-president, Dr. Satterwhite, from Kentucky.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 11, 1895.

	Cases.	Deaths.
Tuberculosis	101	69
Typhoid fever	4	3
Scarlet fever	91	13
Cerebro-spinal meningitis	2	2
Measles	277	24
Diphtheria	230	48

A Temperance Drink.—The *Medical Times* says that there is a great boom in temperance saloons in the East End of London. The public-houses are deserted, and the "ginger-pop" store is besieged by clamoring crowds of thirsty souls, and the East-end thirsty one is a masterpiece of his kind. This sudden conversion after temperance lecturers, General Booth's Army, and a host of other reforming agencies have failed to make an impression on the imbibing proclivities of the East-ender, has puzzled the local social reformers sorely. The clew to the mystery has, however, been discovered by Mr. Stokes, public analyst for Bethnal Green, who has analyzed a sample of ginger wine, sold at a temperance beverage store, which contained ten per cent. of proof spirits, an alcoholic strength just double that of the ordinary beer sold at the public-houses in the neighborhood.

Period of Infection.—The Pennsylvania State Board of Health has adopted the following regulations in the diseases mentioned below :

Small-pox.—Six weeks from the commencement of the disease, if every scab has fallen off.

Chicken-pox.—Three weeks from the commencement of the disease, if every scab has fallen off.

Scarlet Fever.—Six weeks from the commencement of the disease, if the peeling has ceased, and there is no sore nose.

Diphtheria.—Six weeks from the commencement of the disease, if sore throat and other signs of the disease have disappeared.

Measles.—Three weeks from the commencement of the disease, if all swelling has subsided.

Typhus.—Four weeks from the commencement of the disease, if strength is re-established.

Typhoid.—Six weeks from the commencement of the disease, if strength is re-established.

Whooping Cough.—Six weeks from the commencement of the disease, if all cough has ceased.

Under judicious treatment the periods of infectiousness may be considerably shortened.

Length of Quarantine.—Teachers, or children, who have been exposed to infection from any of the following diseases may safely be readmitted to the school, if they remain in good health (and have taken proper means for disinfection), after the following periods of quarantine :

Diphtheria, twelve days ; scarlet fever, fourteen days ; small-pox, eighteen days ; measles, eighteen days ; chicken-pox, eighteen days ; mumps, twenty-four days ; whooping-cough, twenty-one days. Adults may be readmitted immediately, if they disinfect their clothes and persons.

Subcutaneous Injection of Oil in Cases of Stiffened Joints.—In two instances of stiffened joints, where the inability to move the limb has appeared to arise from rigidity of the tendons and muscular sheaths, I have injected, subcutaneously, olive-oil into the structures, and with some success. I find that a fluid drachm of oil can be injected around the knee-joint without causing any after inflammation or discomfort. In one instance where the elbow was operated on in this way, the patient, a young woman, obtained for the first time some degree of movement after six months' entire fixation from rigidity.—Sir B. W. Richardson, in the *Asclepiad.*

Methuselah was no older than he ought to have been when he died, according to the calculations of Dr. Samuel Wilks. He bases this assertion upon the relative proportion that is believed to exist in animals between the duration of life and that of their immaturity. A few thousand years ago, he thinks, it took much longer for a person to reach full maturity, as the patriarchs seldom married until they were a hundred years old or so. Now, as it is unlikely that they were waiting for an increase in salary before indulging in matrimony it is almost certain that they were still undeveloped. "The principal facts mentioned in the lives of the patriarchs, calculated to guide us," he said, "are the time of their marriage and the birth of their first child. Now, if this be taken as the commencement of manhood, we see how this term is delayed, so that its proportion to the whole duration of life is preserved. Thus, Methuselah lived to be 969 years of age, and his first child, Lamech, was born when he was 187 years of age." We are uncertain whether Dr. Wilks is trying to enlarge his talent for humor, or whether he really believes what he says.

Evils of Quackery.—Quackery is medical practice commercialized, and therefore prostituted. It thrives because the victims are in the majority and are easily reached by lying advertisements. "What is the proportion of sensible people in this crowd ?" asked a patent medicine man of a physician. "About 1 in 10," was the answer. "I take the nine and leave the one to you," said the quack. This represents the majority which help to make the quack rich. The nostrums cost almost nothing ; but the capital is used in advertising, in making pictures of the idiots and feeble-minded who imagine themselves cured ; in placarding fences ; in defacing scenery ; in publishing manufactured certificates ; in ridiculing scientific medicine ; in alarming the credulous ; in claiming false discoveries ; and in vaunting impossible results. But these are the men who make the money. Medicine to them is the nickel-in-the-slot machine. The diagnosis is ready-made to suit every need, and even otherwise sensible people are being educated into quackery and into the belief that every man can be his own doctor and not have a fool for a patient.—Dr. George F. Shrady in *Forum.*

Physicians in Literature.—Physicians occasionally drop into literature. Dr. B. H. Throop's book, "A Half Century in Scranton," though not strictly medical, contains some quaint and interesting reminiscences of practice in the primitive settlements of the anthracite region. We quote : "There was but one physician in the town in 1840 ; he rarely gave any medicine except rhubarb and soda. When called in haste, his patrons requested he would go on foot. He performed all the duties of doctor and nurse for all the country around." Called long distances through the mountains, Dr. Throop often met startling emergencies and improvised means for desperate operations. He relates an amputation of both feet for gangrene in which his operative outfit consisted of a razor and a common hand-saw ; the patient survived. In one chapter he describes the trials and difficulties of a surgeon going out with the first troops in the Civil War, and in another detail, the founding and early history of the first hospital of the coal region. Dr. Throop is eighty-three years old and has shown a fatherly interest in two or three generations of young doctors. His book is well written, and as a history of an important time and region will interest many outside the coal-fields.

CÆSAREAN SECTION VERSUS SYMPHYSEOTOMY, WITH THE REPORT OF CASES.[1]

BY EDWARD P. DAVIS, A.M., M.D.,

PROFESSOR OF OBSTETRICS AND DISEASES OF INFANCY IN THE PHILADELPHIA POLYCLINIC; CLINICAL PROFESSOR OF OBSTETRICS IN THE JEFFERSON MEDICAL COLLEGE; VISITING OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL, ETC.

ANTISEPTIC symphyseotomy has been practised sufficiently long by American operators to afford experience regarding the indications for this operation and its results. The continuous study of the conditions which render patients aseptic, or which predispose to septic infection, is constantly adding facts useful to obstetric operators in choosing an operation. Hysterectomy has been so far perfected, with the aid of the Trendelenburg posture and by recent experience, that Cæsarean section has been advantageously modified by modern hysterectomy. It seems possible, then, in view of these facts to state more definitely the grounds upon which Cæsarean section or symphyseotomy is to be chosen, or declined. During the past few months I have had occasion to deal practically with this question, and offer for your discussion the following cases and the deductions which to my mind they justify:

CASE I.—B. F——, colored, aged twenty-seven, married, primigravida. Applied at the Out-Patient Department of the Philadelphia Polyclinic, requesting attendance at her home for her approaching confinement. Her name and address were taken, but she failed to return for an examination of the pelvis made whenever possible in pregnant cases. On February 13th one of the externe physicians of the Polyclinic was summoned by the patient, and found her complaining of bearing-down pains at irregular intervals. Her confinement was expected about February 20th. On examination, the fundus of the uterus was half-way between the umbilicus and the ensiform cartilage; the back was toward the mother's right side, the head was at the brim of the pelvis, but was not engaged; fœtal heart-sounds were 145; the patient was very small, slender, the vulva and vagina being small and ill developed. Vaginal examination showed the cervix soft and nearly obliterated; the os was dilatable, the pains having apparently little effect upon it. As the patient was excessively nervous, potassium bromide was prescribed, and she was instructed to send for the physician when labor pains became stronger. On February 20th, a week after the first visit, the same physician saw the patient, finding her in true labor. Expulsive pains began the night previous, and had been half an hour apart. Directions were given that the bowels should be moved, a bichloride vaginal douche administered, and instructions were given to send again for the physician when expulsive pains became strong. At 7 A.M., on February 21st, the physician in attendance found her with strong expulsive pains occurring every three or four minutes. The os was the size of a dollar; the membranes were unruptured; the occiput was anterior and toward the right side. Strong uterine contractions continued for two hours, when they began to grow weak. Whiskey and quinine were administered, when the pains became stronger; the head partially engaged, but made no progress. Dilatation became complete, and the membranes ruptured. At 11 A.M. slight hemorrhage occurred without the descent of the head. Dr. W. H. Wells, Instructor in Obstetrics in the Polyclinic, was then summoned, and upon measuring the pelvis found its dimensions to be as follows:

	Ctm.
Anterior superior spines	22
Crests	23½
Trochanters	27½
External conjugate	19

An attempt was made for several hours to secure engagement of the head by placing the patient upon a padded pail, the only substitute for a confinement-chair which the patient's room afforded; this posture, with suprapubic pressure, failed to secure engagement.

Under ether, a cautious attempt was made to secure engagement by the use of Simpson's forceps, accompanied by suprapubic pressure; this attempt failed, and I was summoned to see the patient. I found her, at six in the evening, in fair condition, complaining of excessive pain occasioned by very strong uterine contractions. The strength of these contractions was sufficient to occasion fear lest rupture of the uterus should supervene. The patient's pulse was good, the fœtal heart-sound was slow, and seemed intermittent. On vaginal examination, a very large caput succedaneum was present; the vertex presented, and was turned toward the right side of the pelvis, the head not having engaged. Suprapubic pressure caused the anterior parietal bone to rotate downward, but failed to secure engagement. There was almost constant oozing of blood from the vagina, which gave rise to the suspicion of a low attachment of the placenta, although vaginal examination failed to reach the placenta. After the administration of a hypodermic injection of morphia, the patient's pains became slightly less violent, and the fœtal heart-sounds were stronger and ceased to intermit.

As the patient had but one small bed-room, and an insufficient supply of hot water was obtainable, I directed the husband to take her in a cab to the Polyclinic Hospital. On arriving at the hospital at 8 P.M., the fœtal heart-sounds were sufficiently good to justify an attempt to save the life of the fœtus. Symphyseotomy was chosen, because the disproportion between the head and the pelvis did not seem so great as to be insurmountable by this operation. Symphyseotomy was readily performed by suprapubic incision, a sound being held in the urethra, and the urethra drawn to one side by Dr. Wells. Upon opening the symphysis, the two halves of the pubic-joint separated an inch and a half, the head immediately descending to the pelvic floor. The child was extracted with Simpson's forceps, asphyxiated, but resuscitated. The child's head measured as follows:

	Ctm.
Occipito-frontal	13
Suboccipito-bregmatic	11
Occipito-mental	14
Maximum	15
Bi-parietal	11
Bi temporal	9
Trachelo-bregmatic	10

Attention is called to the bi-parietal diameter and also the suboccipito-bregmatic, both of which were

[1] Read by invitation before the Section on Obstetrics, New York Academy of Medicine, April 25, 1895.

considerably larger than in the average fœtal head. The placenta was found, as diagnosticated, attached to the border of the lower uterine segment posteriorly.

It was removed, the uterus douched with creolin and tamponed with iodoform gauze. A slight laceration of the pelvic floor in the median line occurred, but it was not thought justifiable to delay to close it. The symphyseotomy wound was tamponed with a strip of iodoform gauze, and closed, with the exception of the lowest suture, which was inserted, but left untied. The urethra was patulous, and although the anterior vaginal wall had sustained injury by being drawn against the cut ends of the pubic bones, still the anterior vaginal wall had not been perforated. The usual dressing after symphyseotomy, and a strong band of adhesive plaster eight inches wide placed about the trochanters, were applied. During the first twenty-four hours after the operation the patient was unable to empty the bladder, and several attempts were made by nurses and residents to pass a catheter. These attempts were not successful, and accordingly, twenty-four hours after the operation, as the parts were excessively sensitive, although not swollen, the patient was partially anæsthetized with ether, and the catheter passed by Dr. Wells. The urethra was found lower down and to the left of its normal position. It was uninjured. It was noticed at this time that the tip of the finger could be passed into the symphyseotomy wound through the anterior wall of the vagina. Considerable oozing of blood occurred from a small vessel in the vaginal wall, which required the application of a ligature. The vagina was tamponed with iodoform gauze after the intra-uterine tampon had been removed. The vagina was thoroughly douched and an antiseptic vulvar dressing replaced. During the night following the patient passed her urine spontaneously. Her temperature was 100.2° F.; pulse, 110; respirations, 26. The lochia was scanty, but was bloody and without odor. The lower portion of the abdomen was slightly distended. The patient, however, continued to be excessively restless, suffered from abdominal distention, although her bowels were moved thoroughly by enemata, calomel, and salines. Her temperature did not exceed 102° F., and remained between 101° and 102° F. The secretion of milk did not occur, the patient's strength failed, and she died on the afternoon of the third day following her delivery. Her child survived, and was given to the care of her relatives.

A post-mortem examination was made a few hours after death, and culture media were inoculated from the vagina, from the symphyseotomy wound, from the abdominal cavity, and the uterus. The abdomen was distended and tympanitic. Upon opening the peritoneal cavity, sero-purulent fluid was found in its lower portion. No adhesive inflammation was present. The cavity of the uterus measured five inches in length. The symphyseotomy wound presented no evidence of inflammation. The cavity of the uterus was normal, the placental site situated in the lower uterine segment on the right side. A small fibroid was situated in the posterior wall of the uterus. No evidence of inflammation or suppuration was found about the vagina or the symphyseotomy wound. The two connected by an aperture admitting the tip of the index finger. The intestines were distended with gas, but contained but little fecal matter. The anterior surface of the bladder was injected, and seemed in the first stage of inflammation.

The tubes inoculated from the body of this patient were sent to Dr. D. B. Kyle, Instructor in Bacteriology in the Jefferson Medical College, for examination. The report from this examination showed streptococci and staphylococci from the vagina and from the uterus. No cocci were found in the peritoneal cavity, but the bacillus coli communis was present. An examination of the patient's urine, taken shortly before her death, revealed nothing of pathological significance.

The infection and death of this patient after symphyseotomy, in view of the success which ordinarily attends this operation, are not at first sight readily explained. Those who had to do with the patient are accustomed to practise antiseptic precautions which are successful in other cases. During the first part of her labor she was under the care of a negro nurse or midwife, who had no knowledge of antisepsis. The responsibility for her infection must primarily rest with the operator, but the variety of infection found in the abdominal cavity is of more than common interest. While we are familiar with the fact that the bacillus coli communis may infect the abdominal cavity, our attention has been recently called by Walthard [1] to the fact that streptococci and other germs found in the vagina before labor do not become virulent and capable of producing septic infection, except in cases where the resisting power of the tissues is lowered by prolonged and difficult labor, by operative injury, or by debilitating and exhausting disease. The injury of the anterior vaginal wall which this patient sustained has occurred in the experience of others, and need not necessarily have led to infection. The occurrence of this injury is best explained by referring to the unusual width of the fœtal head, 11 ctm., instead of 9½ ctm., the normal. The occiput was delivered anteriorly, the head putting the vagina upon the stretch, and bringing the anterior vaginal wall strongly up against the two halves of the severed pubic-joint. It is difficult to see how such injury can be avoided in patients in whom the vagina and vulva are but little elastic, or very poorly developed. Negro children often show unusual breadth of skull and bi-parietal diameter in the skull above the normal size.

In considering this case, I have been impressed by the diminished power of resistance which a young and ill-developed woman possesses when in prolonged and impossible labor. The case has been to me a practical demonstration of Walthard's investigations, which show that although antiseptic measures ordinarily successful be carried out in such a case, germs either present in the vagina during pregnancy, or introduced by the obstetrician or his assistants during labor, become actively virulent in such a patient. No way readily suggests itself by which a large head can be extracted through a small and undeveloped vagina after symphyseotomy without injury to the vagina more or less extensive. This fact leads me to believe that in choosing symphyseotomy, the obstetrician must study carefully the size and elasticity of the cervix, vagina, and vulva, as well as the dimensions of the pelvis.

In connection with this subject, attention is drawn to the interesting paper of Audebert in the *Archives de Toxicologie*, No. 2, 1895.

Case II.—E. R——, colored, aged eighteen, a small, ill-developed woman, pregnant, was admitted to the Philadelphia Hospital during the past winter. In the month of February my attention was called to her by the resident staff, her diminutive size suggesting a possibly difficult labor. Her father, mother, several sisters, and a brother had died of tuberculosis. She was illegitimately pregnant, and without friends. Upon examination, March 8, 1895, the breasts were large and well developed. The fundus of the uterus was midway between the umbilicus and the ensiform cartilage. The fœtus was in breech presentation, the back to the mother's left side. Her height is 4 feet, 8 inches. The patient's pelvis measured:

	Ctm.
Iliac spines	23
Iliac crests	24
External conjugate	17
True conjugate	7½
Right diagonal	21
Left diagonal	20
Trochanters	29

Fœtal heart-sounds, 160

[1] Archiv für Gynäkologie, Band 48, Zweites Heft, 1895.

The patient's general condition was fairly good. As complicated labor was expected in her case, she was transferred to the Maternity Pavilion, where frequent examinations of her urine were made, where she was given warm baths frequently, and put in good condition for any operative procedure which might become necessary. On March 28th she was examined under ether, the head being found to present, when, by suprapubic pressure, the head was made to partially engage in the brim of the pelvis. It did not, however, descend, but upon firm pressure the anterior parietal bone rotated downward and backward, the head remaining at practically the same level above the pelvis. It was thought best, as the patient was near the termination of her pregnancy, to induce labor, with the hope that she would bring the head into the pelvis by uterine contractions. At 11 A.M., March 29th, induction of labor was begun by a bougie. Pains began shortly afterward, three minutes in length, occurring frequently. In the evening, the bougie, which had been forced out, was replaced, and the vagina tamponed with gauze.

March 30th, 9 A.M.—A finger could be inserted within the os, the cervix being obliterated, the head could not be felt by vaginal examination, but remained freely movable above the brim of the pelvis. At two in the afternoon, the patient having been in labor twenty-seven hours, my colleague Dr. Hirst was summoned in consultation. The patient was so restless that a vaginal examination could be made with great difficulty, not only from her resistance, but because the vagina and vulva were so small as to make a thorough examination almost impossible. Dr. Hirst concurred with me in the opinion that delivery by abdominal incision offered the best chance to mother and child. In consideration of the patient's tuberculous family history, her friendless condition, and illegitimate pregnancy, I decided to make subsequent impregnation impossible by removing the uterus, tubes, and ovaries. The patient was removed to the clinical amphitheatre of the hospital, where cœliotomy was performed with the kind assistance of Dr. Hirst. The membranes were unruptured, the placenta was in the line of incision through the uterus. The child was readily extracted in the usual method of performing Cæsarean section. The broad ligaments were then ligated, the uterine arteries ligated, the uterus amputated at the cervix, the edges of the stump brought tightly together by a continuous fine silk suture, the stump dropped, the abdomen being closed without drainage. The child inspired liquid at the time of birth, and was partially asphyxiated, but revived.

With the exception of rapid pulse during the first week of the puerperal period, the mother has done well. The dressing applied at the time of operation was removed fifteen days after the operation. Union had occurred by first intention; the stitches were taken out and the wound redressed. The patient has had an abundant supply of milk, and has nursed her own child and assisted in furnishing nutriment for another as well. The measurements of the child's head were as follows:

	Ctm.
Bi-temporal	7½
Bi-parietal	8¼
Occipito-frontal	11¼
Occipito-mental	12½
Trachelo-bregmatic	10
Occipito-frontal circumference	32
Fronto-bregmatic circumference	29
Occipito-mental circumference	20½
Length	42½
Weight when born	4 lbs.
Present weight	4 pounds, 15 ounces.

It is evident from a comparison between the size of the mother's pelvis and the measurements of the child's head that the method of delivery chosen was based upon the relative indications. The indication for delivery by cœliotomy arose, in my judgment, not simply from the small size of the mother's pelvis, but from her ill-developed birth-canal, and from her failure to bring the child into the pelvis by spontaneous labor. When I first saw the patient, it seemed to me that in all probability she could deliver herself with, at most, assistance by forceps and double episiotomy to permit the extraction of the child. Her failure to bring the head to engage, and the failure of labor pains to cause dilatation and to initiate the normal phenomena of labor, seemed to me to indicate that the best results for mother and child would follow prompt delivery by surgical methods.

The consideration of this subject cannot be complete without reference to the permanent results of Cæsarean section and symphyseotomy. The fact that the Sänger Cæsarean operation leaves the patient exposed to subsequent pregnancy, and a possible repetition of the Sänger operation, is brought forcibly to my mind by a patient upon whom I operated by the Sänger method a year ago. As she is a married woman, and no request was made that subsequent impregnation be prevented, the Sänger method was chosen. She and her child made a good recovery, but her disappointment and fear upon finding herself again pregnant lead me to question the wisdom of thus allowing her to be exposed to the dangers of a second operation. Her present pregnancy has been uneventful, and can of course be terminated by induced labor, with the possibility of securing a living child. She stated that during the first part of her present pregnancy she suffered from distress caused by the adhesion of the uterus to the anterior abdominal wall, but as pregnancy progressed that has grown less.

The permanent results following hysterectomy upon the pregnant womb must be essentially those which follow the same operation for other conditions. Delivery by cœliotomy, followed by hysterectomy, must be considered preferable to the Porro operation in the more speedy convalescence of the patient and in her subsequent condition. As regards the permanent results of symphyseotomy, I have had under observation for a year two women and their children whom I delivered by symphyseotomy. In both cases the pelvis has been several times examined by an orthopedic surgeon and myself, with failure to find any abnormality in either case. So far as the pelvis is concerned, the results of the operation in these cases have been entirely satisfactory. In one case, a poorly developed young woman with a small birth-canal, thickening of the anterior vaginal wall below the urethra called for anterior colporrhaphy, which relieved the irritable condition of the urethra.

In conclusion, experience in five symphyseotomies leads me to believe that the operation is a child-saving one, as in these cases the children have been saved, when otherwise no alternative remained but craniotomy, or delivery through the abdomen. One of these cases was taken from a tenement-house, suffering with pneumonia, and survived the operation two days. Bacteriological examination of her genital tract and the symphyseotomy wound showed no infection. The case reported leads me to believe that symphyseotomy is most successful in women not weakened by prolonged labor, in women where slight contraction of the pelvis exists, where no great disproportion in the size of the head and pelvis is present, and in women in whom the vagina and vulva are well developed and distensible. The Sänger operation is indicated where marked disproportion between the head and pelvis exists, as shown by the failure of the head to engage; where the vagina and vulva are poorly developed and not distensible, and where the patient is a married woman, and is willing to run the risks of further impregnation. Where a patient is without home and friends, illegitimately pregnant, of poor physical constitution and in danger of further illegitimate pregnancy, delivery by cœliotomy, followed by hysterectomy, is advisable.

SOME CLINICAL FACTS ABOUT YELLOW FEVER.

By J. EDWARD STUBBERT, M.D.,

CHIEF SURGEON NICARAGUA CANAL.

During the past few months an epidemic of yellow fever has visited San Salvador, and the following clinical facts may be of interest, being in some instances so diametrically opposed to the written history of the disease.

The habitat of yellow fever is popularly supposed to be confined to the Atlantic coast of Central America, the waters of the Gulf of Mexico, Western Mediterranean, etc., in the zone between 42° north and 35° south latitude: and Macdonald says (Reynolds system), "Never, except as in a very few instances transiently conveyed by infected ships, has it been seen on the Pacific."

Natives of Central America will tell you, however, that not only is the disease well known and of frequent occurrence on the Pacific coast, but that at regular cycles it visits the cities of the interior in epidemic form. *A propos* of this, I have been informed that some twenty years ago yellow fever swept through this country, carrying death through many inland towns at a considerable elevation above the sea.

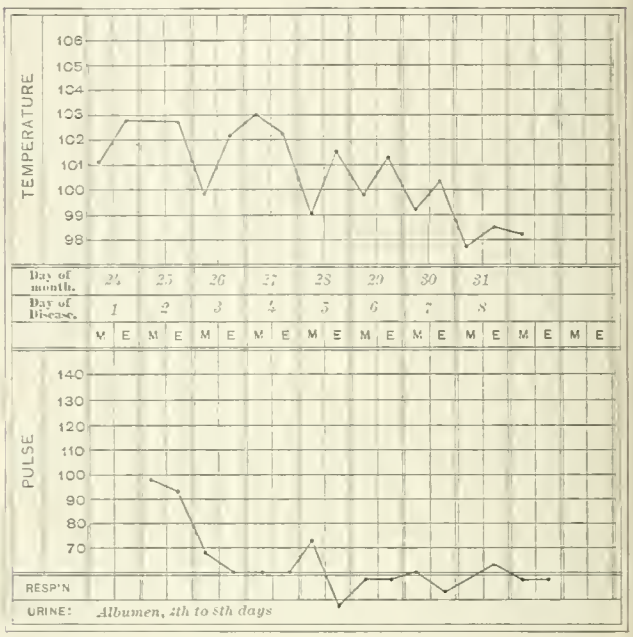
In February the writer was suddenly summoned on board the U. S. S. Ranger, whose surgeon had died of "yellow fever, contracted in the Pacific port of Amapala, Honduras," where the disease was reported to have existed in epidemic form the previous year.

The following July I was called to the U. S. S. Bennington, lying at La Libertad, San Salvador. Yellow fever was then reported to be present in the port, and Captain Thomas was very anxious to learn the nature of the disease on his ship. The surgeon, Dr. Hibbett, and several of the wardroom officers and crew were ill. These cases, however, were easily diagnosed as malarial remittent fever, that of Dr. Hibbett being of the pernicious icteric variety. On the following day eight new cases developed and the ship was ordered home. I have since received a letter from Surgeon Hibbett, citing a case which developed shortly after leaving the port, and which I judge to have been a true case of yellow fever.

At about this time teamsters plying their trade between La Libertad and San Salvador, the capital, a city of about thirty-five thousand inhabitants, and situated two thousand two hundred feet above the sea, began to be stricken with the disease on the road, and were brought into the city to be distributed as so many foci of infection in their several homes. The disease now spread rapidly among the poorer classes of the native population, and erelong made its appearance among those of higher social rank. The members of the foreign colony naturally contracted it more quickly than natives of similar social status, and almost invariably the type in their cases was more severe. About seventy-five per cent. of the foreigners attacked were my patients, and it is from the record of these cases I have drawn the clinical facts to be noted.

I have gone thus fully into the question of the geography of the disease as so much has been said and written about its confinement to the Atlantic coast of these Central American countries; and I wish to state that during all the time of active work on the Nicaragua Canal we did not have on our hospital rolls a single case of yellow fever; that, also, careful research on my part failed to discover the record of a case of yellow fever at any time on the Atlantic coast of Nicaragua; that the only authentic cases that have been noticed in that country occurred in Corinto, a Pacific seaport, and in Chinendega and Leon, two cities on the Pacific side, closely connected with Corinto by rail. This fact, that never has a case of yellow fever been known to occur anywhere along the proposed Nicaragua Canal route, is a matter of great interest and encouragement to Americans interested in that great enterprise.

Invasion.—A great difference of opinion exists regarding the manner of contracting this disease. Native physicians will visit a dying patient, in a room reeking with the odors of black vomit and intestinal hemorrhages, arrayed in evening dress, and from there go, without taking any precautions, directly to a crowded ball-room. While this seems to me an unjustifiable risk to take, nevertheless the disease has not, as far as I know, been traced in its origin to exposure of this sort. On the other hand, at least seventy-five per cent. of those persons who, in the capacity of nurses, were constantly exposed to the air of the sick-room fell victims to the disease within ten days from the first day of exposure. Most of the cases developed about five days after exposure to the fumes of black vomit, and I have not on record any case that was contracted by proximity to a patient before the appearance of vomiting or diarrhœa.

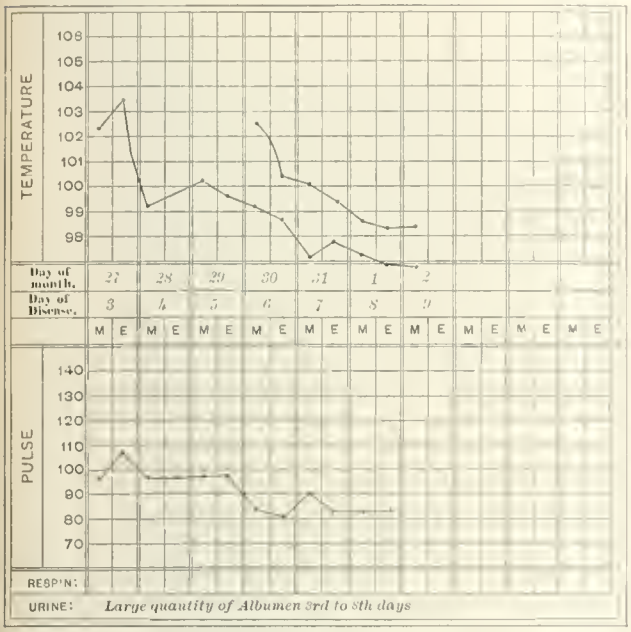


Case of Yellow Fever, Icteric Variety, showing a Remarkably Low Pulse.

So much for the cases where origin could be directly traced to personal exposure to an atmosphere undoubtedly infected with disease germs. These facts seem to bear out the opinion expressed at the Quarantine and Sanitary Convention at New York, 1859, that short visits to yellow fever patients are apparently devoid of danger to those making them; but on the other hand they contradict the verdict of another high authority who states that "yellow fever cases need not be isolated, but may be placed in public hospitals among other patients." The fact of the portability of the disease has been conclusively proven by this epidemic, but the manner of such transfer still remains doubtful. The fact, however, that the disease appeared in different cities on a route of continuous travel from the first infected port shows the necessity of strict quarantine.

Symptoms.—Few cases were ushered in by the historical chill, but all were preceded by rigors of more or less severity. In most instances, the facial expression was characteristic—congestion of whole countenance and suffusion of the eyes, accompanied with pain in the back and limbs and very severe bilateral frontal and post-orbital headache. The initial temperature was usually about 102° F., and the average maximum, less than 104° F., was reached generally within the first six hours of the disease. The remission occurred in four cases on the third day, in two on the fifth, in all others on the fourth, and lasted, on an average, six hours. The average length of the third stage was three days. Black vomit appeared in most cases as early as the third day, but nausea was present from the incipiency of the

disease. Decrease of the amount of urine was present on the second day in nearly every case, and albumin appeared on the third or fourth day. It was found in large quantities in about ninety-eight per cent. of the cases under observation, and was absent in but two or three instances. In most cases the albumin disappeared suddenly with the fall of temperature during the third stage of the disease, but in exceptional instances traces remained for some time during convalescence. Jaundice was by no means a constant symptom, and in no case was it present before the fifth or sixth day.



Case of Yellow Fever, Algid Variety, showing Difference between Rectal and Sublingual Temperatures. In this case symptoms of albumin were very marked, and from the sixth day the pulse was intermittent. Patient recovered.

Constipation was found in most cases all through the disease; in a few diarrhœa supervened during the third stage, and in one case, where intense general jaundice was present, the defecations were pasty and clay-colored. In at least ninety-five per cent. the mind remained clear until the end of the disease, whether that end was reached in death or recovery. The generally noted slow pulse was present in all cases excepting one. A few were marked by great depression, intermittency of the pulse, algid surface, and during the third stage a great difference between sublingual and rectal temperatures, that in the rectum being the higher, registering in one case 102⅗° F., while the sublingual record was 99⅕° F. In the MEDICAL RECORD, volume xxx., page 263, in an article upon "Malarial Hæmaturia," I called attention to the great confusion in diagnosis in our Southern States between pernicious malarial fever, especially of the icteric variety, and yellow fever. There is really very little difficulty in differentiation, if we remember that in pernicious fever the black vomit appears within the first thirty-six hours, albumin is almost never present, hæmaturia is a prominent symptom, the temperature and disease are both markedly amenable to hypodermic injections of quinine, and there is no pathognomonic stage of remission. Again, pernicious malarial fever usually attacks those who have been the subjects of repeated attacks of malarial diseases. The pulse in pernicious fever is commensurate with the temperature, and the latter often reaches 106° and 107° F. In yellow fever black vomit is rarely seen before the third day. Albumin in the urine is almost a pathognomonic symptom; hæmaturia is, I believe, never seen, excepting in the last stage of the hemorrhagic variety. Quinine has no effect whatever on the duration of the disease, the pulse is abnormally low, the temperature rarely exceeds 103.5° F., and chronic malarial infection of a mild character appears to render one less liable to contract the disease.

Treatment.—Here in San Salvador we have had the opportunity of comparing the treatment of the American, German, and French schools (most of the native physicians being thoroughly imbued with the tenets of the last-named system). Practical results are decidedly in favor of our American method of treatment, the death-rate having been only eleven per cent. among those treated according to the teachings of Professor Loomis and other well-known American authors. To my mind there is no doubt at all as to the beneficial effects of quinine administered during the early part of the first stage; not that it cuts short the course of the malady as in pernicious fever, but because it appears to prevent dangerous exacerbations of temperature, and to render less severe the third stage. Owing to the great danger of suppression of urine, it is my practice to administer nitro-glycerine in $\frac{1}{100}$ grain doses, and after a free flow of urine is established to administer digitalis and salinic diuretics according to circumstances. Vichy and milk in large quantities are used by all schools here. Kola is strongly advocated by the French and German physicians, but I have found it of no special value, and very distasteful to the patient. When vomiting begins, the most successful treatment seems to be a full dose of ipecac, followed by large quantities of tepid water, in turn followed by a hypodermic of gr. ⅛ of the sulphate of morphine, to quiet the stomach. When albuminuria appears, the patients become excessively nervous, throwing themselves constantly from one side of the bed to the other, necessitating very small doses of morphine. I have never found it necessary to administer more than six doses of morphine throughout the whole course of the disease, or to produce emesis by ipecac more than twice. Cracked ice and carbolic acid in peppermint-water are generally sufficient to control the nausea; but where they are not, in spite of the fact that the use of opiates is so strongly condemned, I would always administer them. Enemas of brandy and carbolic acid solution for stimulant and antiseptic effects have proved of great value.

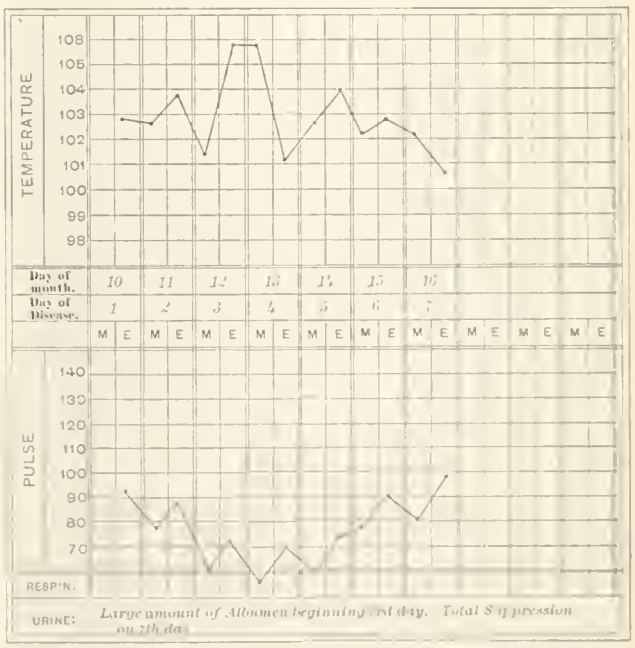


Chart showing the Markedly Depressed Pulse in a Case of Yellow Fever of the Hemorrhagic Variety. Patient died on the eighth day.

Unfortunately, to my mind, so much has been said about yellow fever being a self-limited disease, requiring more than all else good nursing, that it is no uncommon thing to see cases "left to nature" until the critical moment has passed. The treatment, to be successful, must be symptomatic, prompt, and energetic;

and the sheet-anchors are free catharsis, diuresis, and diaphoresis at the beginning, with large doses of quinine hypodermically. After that mild catharsis and free diuresis throughout the disease, emesis, when the vomiting is turning from white to yellow, morphine when necessary to control vomiting or to overcome extreme nervous jactitations, and finally cardiac stimulants when indicated, generally from the beginning of the second stage.

Prophylaxis has demanded the attention of Dr. Gasteazoro and myself, but we have not been able to arrive at any satisfactory conclusion. Perhaps salol in doses sufficient at first to produce optical symptoms and green urine, and subsequently in daily doses of five grains, accompanied by an open condition of the bowels, will be sufficient protection. There seems to be good ground also for the weekly exhibition of small doses of calomel.

THE TREATMENT OF TYPHOID FEVER.

By A. G. HENRY, M.D.,

CORTLAND, N. Y.

I WILL preface my remarks on the treatment of this fever by stating that the mortality ought to, and will, if properly managed, be less than that from almost any other contagious disease. It is a disease that is simple in treatment, easily controlled, and one in which the death-rate should never reach five per cent. In my own practice it is much less than that.

We all know the premonitory and initial symptoms of this fever, so graphically described by Da Costa. Usually when called to a case we will find a temperature of from 100° to 104° F., depending somewhat on the length of time since the sickness began as well as the abruptness of the attack. We will also find that in a few cases looseness of the bowels with tympanites has already supervened. A severe headache is almost always present the first few days or week of the sickness. About the first thing I see to when called to attend a case of typhoid fever is to have the patient removed to a fair-sized, well-lighted room—one in which an abundance of outside air can be introduced at first hand—and to put him in charge of a competent and trustworthy nurse, with injunctions that no one excepting those who are to care for him be permitted to see him. I always tell the patient the nature of his illness, that his fever will probably run from two to three weeks, but that he will feel better inside of a week, and that he will most certainly recover. I think it best at the first visits to impress upon the mind of the patient that his business for the next few weeks is to be entirely devoted to getting well, and I always insist that the sick-room shall be kept quiet, as free as possible from the disturbing influences of the noises of the house; that he shall not try to keep track of his pulse or temperature, or be told any news regarding the doings of his friends or neighbors or the community at large.

Of course the doctor, as well as the nurse, may tell him from day to day that he is doing well, or that he is getting better, as the case may warrant.

Now as to the matter of diet. Diet with me means the withholding of all food of any description for from four or five days to two weeks. The length of time food should be withheld will depend principally upon the behavior of the fever and the condition of the bowels. Usually within from three or four days to a week from the time we first see the patient—if all food is withheld—the fever will have begun to decline, the headache will have disappeared, and then, if there is no looseness of the bowels or tympanites, a small amount of nourishment can be safely given. I commonly give milk, beginning with one tablespoonful at a time, at 6 A.M., 12 M., and 6 P.M. I increase the amount by one tablespoonful a day until a half-teacupful is taken at a time. No more than the last-named amount should be given until several days after the last vestige of the fever has disappeared, when other articles of food may be gradually substituted for the milk.

Under no consideration should food be given oftener than three times a day, and if there should be a relapse or an increase of fever, or a return of bowel troubles, the milk should be at once discontinued until the patient is on the mend again. The milk should be boiled about ten minutes ere giving.

Where there is a dislike for milk, or when it does not seem to agree, I give liquid peptonoids, beginning with two teaspoonfuls at a time morning, noon, and night, and increase by one teaspoonful a day until two tablespoonfuls are given at a time.

As to clothing, the patient should be robed in but a single garment—a night-shirt of plain unstarched cotton or linen—and this should be changed one or more times a day, depending largely upon the amount of perspiration present.

The bed-linen should be changed every day. The nurse should see that the feet and hands of the patient are always warm, and he should be covered but slightly, especially during the height of the fever. His wishes in respect to the amount over him may usually be safely consulted.

An abundance of fresh outside air should be admitted to the sick-room at all hours of the day and night.

Now as to the use of water as an outside remedy. Whatever merits the tubbing system may have, it seems impracticable to carry out the treatment in but few cases in private practice, and in any event I think as favorable results may be attained by other methods of procedure. The patient should be bathed every two to six hours in water of a temperature somewhere from 75° to 90° F. The hotter he is as a rule the colder should the water be. Particular attention should be given to the back. The spine should be well wetted its whole length, for the cooling and tonic effect of the water.

When we come to the subject of medication I am free to state that I think almost as much harm is done by the prevailing drugs administered as by the faulty way of giving food. If there is anything more destructive than quinine in its effects on the organism in general, and the nervous system in particular, when given for its antipyretic action in a case of typhoid fever, it is the coal-tar products. But some one has remarked—and it seems to be about the only redeeming feature of the last-named remedies—"They sometimes enable the patient to die with normal temperature."

Now, although I doubt not that fully nineteen out of every twenty would recover under the treatment outlined above, yet I think there are a few medicines, given when indicated for their direct effect, which are decidedly beneficial. Foremost among these is aconite in small doses. But the doses must be small—not to exceed from five to ten drops of the tincture in a tumblerful of water, of which a teaspoonful may be given once an hour during the waking hours of the patient. Aconite in these doses will modify the catarrhal trouble of the lungs which is almost always present; it is an excellent stimulant to the capillary circulation of the skin, tending to keep it moist, as well as a tonic to the heart's action. At the beginning of the illness or during what may be considered the congestive stage of the fever, usually accompanied by persistent headache and sometimes commencing tenderness in the iliac region, I think benefit is attained by the use of belladonna. This may be added to the aconite, ten drops to the tumblerful of water, and given every hour. I think it well to continue the belladonna until the headache has disappeared and the tenderness in the bowels is relieved, or until there is a decided looseness of the bowels, when it should be dropped. Of all the remedies I have ever used for diarrhœa and the tympanites usually accompanying it I like baptisia tinctorium the

best—five drops of the fluid extract added to the tumblerful of water containing the aconite. I have used no other remedy for this symptom for years. I use no outside applications whatever for the bowel trouble.

One of the most important things in the treatment of this fever is yet to be mentioned—the administration of large quantities of pure, soft water. This may be given cold or hot, as best suits the whim or fancy of the patient. Water is the absolutely essential thing in the successful management of typhoid fever. I always insist on patients taking it often and in large quantities. When they do not seem inclined to take enough voluntarily I have the nurse give from one-third to one-half of a teacupful every hour when the medicine is administered.

We occasionally find in persons past middle life those suffering from organic heart disease. These have to be watched closely, especially toward the latter part of the fever. If in such we discover evidences of heart-tire digitalis in from six- to eight-drop doses of the tincture may be given every six or eight hours. If relapses occur they are to be treated as the original attack.

In conclusion I would state that in a general practice extending over a period of twenty-one years I have had but two cases of hemorrhage of the bowels, neither proving fatal; and since August, 1888, or since I adopted the method of feeding and general treatment described above, I have not had a single case of this fever which was fatal. I have treated from fifteen to twenty-five cases each season.

Clinical Department.

AXILLARY ANEURISM, WITH SUCCESSFUL LIGATION OF THE SUBCLAVIAN ARTERY.

By W. E. WATERS., M.D.,

SURGEON, U. S. A., COLUMBUS BARRACKS, O.

Corporal Charles S——, Company K, Seventeenth Infantry, on duty with Recruit Detachment at Columbus Barracks, O., is forty-three years of age, and has been in the army continuously for eighteen years. He was admitted into hospital December 3, 1894, with aneurism of the left axillary artery, which was situated principally in the second part of its course, but extending beyond the border of the pectoralis minor muscle into the axilla.

The patient was a man of large physique, and general good health, except a mild attack of subacute rheumatism, for which he was not taken on sick report. He has had no physical ailment for many years, until this aneurism appeared. He had been admonished of its presence, by more or less continuous pain, for two or three months, but did not apply earlier for medical treatment, as he supposed it was a rheumatic attack that would disappear without treatment. He was not conscious of the enlargement in the axilla, which had become a tumor measuring about an inch and a half, until it was discovered by the medical officer attending sick call. It had not interfered with the discharge of his duty as instructor of recruits, which duty required the frequent use of the shoulder-joint, in demonstrating the numerous motions in the manual of arms. He was not aware of the artery ever having been injured; he has had no history of syphilis, of gout, or of rheumatism, save the mild attack above referred to; was not of intemperate habits, nor was there anything in his physical condition pointing to the existence of an atheromatous degeneration, or any other disease of the arteries predisposing to aneurism.

The only circumstance in the life and habits of the patient suggesting an exciting cause of the aneurism that I could discover, after the closest scrutiny, was the very continuous exercise of drilling recruits, frequently requiring the extending of arms vertically above the head, causing tension of the arteries in the axilla.

The following is the surgical history of the case: December 3, 1894, he reported at sick call, complaining of pain in the axilla and in the arm and forearm. He was taken into the hospital, and an axillary aneurism unmistakably diagnosticated. There was not a common symptom absent, and it afforded a typical case for the study of an uncomplicated aneurism of the second and third portions of the axillary artery. After his admission the pain increased from day to day (except during a short time to be referred to hereafter), and soon extended to the hand, which became the most painful part, first involving the thumb, index finger, and middle finger—the parts supplied by the terminal branches of the median nerve—with its greatest intensity in the tips of the fingers. He described it as a "burning, stinging sensation," in contradistinction from the aching pain he had previously felt in the arm.

About this time, that is, ten days before the ligation of the artery, paralysis of the extensor muscles, deriving their nerve-supply from the musculo-spiral, was first discovered, with impaired power to extend the hand, and in a day or two thereafter the paralysis had become complete, with the typical "wrist-drop." At this time the loss of sensation, also in the back of the hand, was noticed. The flexor muscles of the forearm had but slight loss of contractility, while the paralysis of the extensors was complete. The treatment prescribed was rest in bed with restricted diet, and the administration of iodide of potassium, in half-drachm doses, combined with three minims of tincture of aconite, three times a day. Digital compression of the subclavian artery over the first rib was tried, and there was an unsuccessful attempt to make continuous pressure with a long rubber bandage extending over both shoulders and the perineum, as recommended by one of our Philadelphia surgeons. The already severe pain caused by the pressure of the tumor on the contiguous nerves precluded any attempt to make direct pressure over the aneurism.

The patient's irritable condition, arising from his unusual confinement—for he had always led an active life—and the pain he was constantly suffering, prevented any co-operation on his part in the mechanical method of treatment that was tried. He was given, nightly, a hypodermic injection of morphine and atropine, at first a quarter of a grain of the former, and 1 to 100 of the latter, but this was gradually increased to one-half a grain of sulphate of morphine and 1 to 50 of atropine. As a rule one injection at night was sufficient, but some days a second and a third in the twenty-four hours were necessary to relieve the intense pain.

A few days after the commencement of treatment there appeared to be a clot forming in the aneurism. A diminution in its size, and much less pain, offered a delusive hope of a cure. But the improvement was of short duration, and soon the tumor increased in size, with aggravation of all the symptoms. The more conservative treatment having failed it was decided to ligate the subclavian artery, in its third division, outside the scalenus anticus muscle. The patient was anxious to have the operation performed, notwithstanding he had been informed of its dangers.

On December 27, 1894, I tied the vessel in the part indicated, assisted by assistant surgeons Brechemin and Heyl, of the army, and Dr. Hamilton, of Columbus, O. The operation was performed with antiseptic precautions, in the usual manner, by an incision above the clavicle, from the outer border of the insertion of the clavicular portion of the sterno-cleido-mastoid muscle to the trapezius, just above its insertion. There was a little delay in finding of the artery

[1] A special report made to the Surgeon-General, U. S. A.

because of its unusually small size and feeble pulsation, but the operation was attended by no untoward circumstance, with a minimum loss of blood, and the division of a very few of the smaller vessels. The ligature used was the carbolized catgut furnished by the medical supply department of the army. The ligated artery was completely occluded, as determined by the cessation of pulsation in the aneurism and at the wrist, as well as the cessation of the bruit, which had been very distinct up to that time. The warmth of the hand and arm was maintained, uniformly and constantly, by enveloping them in thick layers of cotton wadding.

The wound of operation healed by first intention throughout, except where a roll of iodoform gauze had been inserted to promote drainage should suppuration occur. There was no rise of temperature, at any time after the operation, except for an hour or two, when it rose to 100° F., attributable doubtless to the ether intoxication, as the struggles of the patient were long and violent during the administration of the anæsthetic and also as he regained consciousness. After the operation the pain had so far subsided that for several nights the patient slept soundly without an anodyne. Unfortunately the "wrist-drop" continued, and there was a persistent numb, painful sensation in the hand, but none in the arm.

January 17th I commenced the use of a mild faradic current of electricity, to which the muscles of the forearm gently responded, more in the flexors than the extensors. A few days later massage was added to the treatment. The patient's general health has been good, and in suitable weather he has taken out-door exercise.

January 30th, resumed the administration of iodide of potassium in the doses given before the operation. There have been no objective symptoms of a syphilitic taint, but the tolerance of the iodide, in the earlier history of the case, suggested the possibility of such an infection; hence the resumption of the iodide, which was also indicated in promoting the absorption of the tumor. The advisability of a second operation for the removal of the tumor from the axilla, to relieve the paralysis, has been considered, but in view of the diminishing size of the tumor, of the nerves having adapted themselves to their new environment, and the slight improvement that has taken place (all considered in connection with the uncertainty of benefit arising from the operation, and the difficulties attending its performance), I decided not to operate.

Upon my recommendation the patient was sent to the Army and Navy Hospital at Hot Springs, Ark., where it is hoped that benefit may arise from the use of the waters, and a change of climate from the unusual rigorous weather of this locality, which has to a great extent prevented out-door life.

In a letter received on March 14th from the patient, written at Hot Springs, Ark., where he has remained since he left this place, he states that he is gradually regaining the use of the fingers and wrist-joint, and that the tumor in the axilla is diminishing in size.

COLUMBUS BARRACKS, O., March 15, 1895.

AMOUNT OF MORPHINE TAKEN BY HABITUES.

DR. J. P. KENNEDY, of Wingham, Ont., writes: "I have noticed in the recent numbers of the MEDICAL RECORD several articles on the maximum doses of morphine habitues. I may, perhaps, be permitted to report a case which came under my observation over a year ago. I. L——, a young man twenty-six years of age, apparently strong and vigorous, muscular system very fully developed, who used 60 grains per diem, hypodermically—30 grains night and morning. The patient desired to be cured of the habit, but complained of no ill effects from its use. I cannot think the case that Dr. Groom, of Iowa, reports very extraordinary; for although my experience with such cases is somewhat limited, yet I have met scores of cases using 30 grains per day."

PERMANGANATE OF POTASSIUM IN OPIUM POISONING.

BY J. G. HAYES, M.D.,

WILLIAMSBURG, MASS.

AT 8.40 A.M., on April 25th, I was called to see a man, sixty-five years of age, who had taken, with suicidal intent, one and one-half ounces of laudanum. He had taken the poison at 8.05 A.M., not having eaten anything since the previous evening. On my way from my office to the patient, which was only a short distance, I recalled to mind the "Report of Cases of Opium Poisoning Successfully Treated by Permanganate of Potassium" by Dr. William Moor, of New York, which I had recently read in the MEDICAL RECORD of March 2, 1895. Being somewhat interested in this subject I decided to try the above-mentioned treatment and to watch the result carefully. I found the patient at 8.45 A.M. walking back and forth in his room very much excited, but being an intelligent man he gave me definite answers as to the time he took the drug and the quantity. At this time his gait was becoming somewhat unsteady; eyelids drooping; pupils contracted to pin-holes; pulse, 85; respiration somewhat slow. I at once administered 30 grains of the sulphate of zinc in a glass of tepid water and injected hypodermically $\frac{1}{30}$ grain sulphate of atropia. There being no vomiting at the end of twenty minutes, I gave him a heaping teaspoonful of mustard in a glass of warm water and followed this with more tepid water. At 9.25 he vomited a little, but not half of the fluid he had just taken. This was one hour and twenty minutes after he had taken the poison on an empty stomach. At this time he was not able to stand without assistance, but he could answer questions and made an effort to walk, but his limbs would not support his weight.

At 9.30 A.M. the pulse was 85, weak and irregular; respiration, 12; countenance somewhat livid. Not being able to stand he was placed on a bed, and he became immediately unconscious, but he could be roused and would answer. Having procured a solution of permanganate of potassium, 1 grain to the drachm of water, and a hypodermic syringe of $1\frac{1}{2}$ drachms' capacity, I injected 1 grain of the permanganate every half hour till 3 grains had been administered, beginning at 9.30 A.M. At 10 A.M. the pulse was 90 and respiration 10. At 11 A.M. the pulse was 100 and the respiration 6. The patient was in a profound stupor, from which it was impossible to rouse him. I injected 3 grains of the permanganate into the buttock. At 12 M. respiration was 5; countenance livid. Administered 3 grains. At 1 P.M. the pulse was 110, weak and irregular; respiration, 4 or 5 (9 in two minutes). Condition worse than one hour before. Again administered 3 grains, making in all 12 grains of the permanganate. At 1.30 P.M., respiration, 6. At 2 P.M., respiration, 10. At 2.30 P.M., respiration, 12. The patient could be roused so that he opened his eyes and scratched his face and answered questions. At 3 o'clock the man sat up in bed and called for a glass of water. He was allowed to sleep till 4 P.M. When he was roused he was perfectly conscious and was able to walk into an adjoining room without assistance. There was a good deal of inflammation of the tissues where the injections were made; otherwise the patient was all right the next day. I am very certain he took one and one half ounces of laudanum and that he was not accustomed to the use of the drug, but whether he survived as a result of my treatment or in spite of it, I am not certain.

Progress of Medical Science.

Pathology of Infantile Paralysis.—In a recent number of the *Wiener Klinische Wochenschrift*, Dr. E. Redlich publishes a contribution to this subject, the tendency of which is to support the view that in so-called acute anterior poliomyelitis the process is to be regarded, not as confined to the ganglion cells, but as an acute inflammation affecting chiefly the anterior horns of the spinal cord. The paper consists mainly in a description of the cord in a case which terminated fatally a few days after the onset of the symptoms. The patient was a child, aged five months, previously healthy, who became restless, with a high temperature (*The Lancet*). On the fourth day after the commencement of this illness, there was weakness of all the limbs, with loss of voice. Loss of knee-jerks, slight sensory impairment, difficulty in breathing, and transitory difficulty in swallowing were also present. The cranial nerves, except so far as was manifested by a doubtful unilateral weakness of the face, showed no alteration. There was slight feverishness. On the ninth day of the illness there was temporary cessation of respiration, which was repeated on the tenth day, and from which the child did not recover. An examination of the spinal cord showed the presence of an acute inflammatory process affecting the cord throughout its entire length. This process did not confine itself to the anterior horns, although these were chiefly affected. It involved also the remainder of the gray matter, and even the tracts of white matter, in which there were small foci of inflammation. The changes in the anterior horns were most intense in the lumbar enlargement, less so in the cervical swelling, and least of all in the dorsal region. The ganglion cells showed the marks of acute degeneration. Outside the anterior horns, in the posterior horns, in the central substantia gelatinosa, and in a part of Clarke's column, and also in the white matter—especially the lateral and anterior tracts—there were found small areas of inflammation. In the posterior columns only one such area could be discovered. These areas in the white substance seemed to depend upon acutely inflamed vessels, and although they were in the vicinity of the anterior horns they did not appear to be connected with them. The vessels outside the cord, also, especially the artery of the anterior fissure and its branches to the anterior horns, were similarly affected with acute inflammation. Similar foci of inflammation were found in the medulla oblongata and the basal structures similarly grouped around inflamed vessels, but the cortex cerebri seemed to be free from them. The peripheral nerves, especially the phrenic and inferior laryngeal, showed very severe degeneration, and the muscles showed evidences of fatty degeneration. It is, of course, quite open to doubt whether this case was really one of the ordinary type of infantile paralysis. The appearances in the cord suggested the presence in the blood of some toxic material affecting the vessels, and simultaneously or secondarily the structures also of the spinal cord.

The Diet of Epileptics.—The influence of diet upon epilepsy is a matter of peculiar importance in the treatment of the disease. In a certain sense epilepsy is always reflex. The starting-point of a fit must be looked on as an extrinsic irritation, and in many cases it arises from indigestion (*The British Medical Journal*). Errors in diet, however, probably influence epilepsy in other ways than this. The portion of food which is absorbed may be injurious, besides that which, remaining undigested, acts as an irritant; and there is a good deal of clinical experience in favor of supplying a minimum quantity of meat in cases of this sort, not on account of it producing indigestion, for it is often digested quite well, but because of its imagined effect in increasing the "irritability" of nervous structures—a somewhat hypothetical property, but one based on the same sort of rough observation as is the well-recognized relation between corn and skittishness in horses. The interest of this subject has led us to make inquiries as to the food given to the patients at the epileptic colony at Chalfont St. Peter, and by the courtesy of the secretary we have been furnished with the daily dietary for a fortnight. Breakfast was on each day the same, consisting of oatmeal porridge, with new milk or sugar, tea, and bread and butter. Dinner consisted of roast or boiled or hashed beef or mutton, with cabbages and potatoes, followed by a rice, sago, tapioca, suet, or jam-roll pudding. Tea was accompanied with bread and butter or dripping, or sometimes golden sirup, or currant-cake. Supper generally included some pudding, with milk and bread, varied occasionally with soup instead of pudding. On Fridays fish was given instead of meat. It must be noted that all the inmates are men. At the present time they are nearly all engaged in outdoor work for a considerable number of hours a day, which probably enables them to assimilate without difficulty a somewhat freer diet than would be possible in other conditions; and it is not improbable that the improved nutrition, due to the combination of active work with a dietary better than could be digested in a sedentary life, may be a not unimportant factor in relieving the disease.

Lesions of the Stomach.—According to Professor Hayem acute parenchymatous gastritis is a process beginning in the glandular elements, and in the pure form is independent of any leucocytic infiltration. The portion of the stomach first affected seems to be the cardiac, and thence the lesion spreads, with the result that the pyloric portion becomes completely changed, losing its distinctive character, and finally being indistinguishable from the cardiac end. He maintains that there are no special cells for the secretion of hydrochloric acid, and in support of this he points out that in the stomach of the new-born child the parietal cells are well developed, although gastric digestion is carried on without any hydrochloric acid being present. Again, he has found no increase of parietal cells in the adult stomach in cases of hypersecretion of this acid, but that in these cases the increase in amount of hydrochloric acid seemed to correspond with the transformation of pyloric into peptic glands, or, in other words, with the disappearance of the alkaline pyloric secretion. The debated question of the presence or absence of hydrochloric acid in cancer of the stomach has, according to the author, lost all interest. The state of digestion, he says, depends in cancer, as in any other gastric condition, on the condition of the gastric mucous membrane. Cancer is developed most frequently in hypopeptic or apeptic cases, and it is in such that free hydrochloric acid is absent, while histological examination of the stomach shows "atrophic gastritis." On the other hand, a hyperpeptic condition may exceptionally be found in persons suffering from gastric cancer. In such cases one would expect to find a different anatomical condition, and in such a case he quotes Lion as having found well-marked parenchymatous gastritis. Gastric ulcer, on the other hand, is most frequent in hyperpeptic cases, and the dominant lesion is a form of gastritis more or less parenchymatous in nature. The pathogenesis of gastric ulcer, however, is a very much more variable question than that of malignant disease.—*La Semaine Médicale.*

Artificial Light.—A Parisian opthalmologist says that the incandescent electric light is the least harmful to the eyes of all artificial light. Next comes the light of a good kerosene lamp, after that candles, and the worst of all is ordinary gas-light.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, May 25, 1895.

PSYCHOLOGY IN THE EDUCATION OF THE PHYSICIAN.

THE Trustees of the Women's Medical College of the New York Infirmary have, during the past winter, given their students a number of opportunities to listen to lectures by authoritative speakers, upon the relation in which the doctor's education and life-work places him or her to other scientific fields than those with which the medical student is most naturally concerned. This wise enterprise must be heartily commended by anyone who realizes that the very fulness of the studies which modern students of medicine are compelled to undertake, itself involves the danger that they may lose sight of the relation of their work to the general movement of scientific thought.

The address upon the important subject with which we here deal was delivered by Mr. Henry Rutgers Marshall, the architect, who has lately designed the new buildings occupied by the college, but who is also known to the medical profession as a psychologist who has paid especial attention to the nature of pain, and who has made certain contributions to the theory of the physical basis of pain that have attracted so much attention.

Mr. Marshall's presence as a lecturer before a body of medical students was indeed a strong argument in favor of his claim that the doctor ought to study psychology; for the intimate bond that exists among the sciences, and especially between psychology and the sciences with which the doctor must become acquainted, is well exemplified when we find that a man who aims to fix his views in reference to the psychology of Art is compelled to make so thorough a study of the physical basis of mental phenomena that he finally appears as a "half-fledged" neurologist, as Mr. Marshall himself expressed it.

It is clearly true that the psychologist and the physiologist are dealing with diverse sides of the burning question as to the relation of mind and matter; and it is as certainly true that if the physiologist is right in his demand that the psychologist shall know the principles of neurological physiology, then the psychologist in his turn is right in demanding that the neurologist shall know a great deal about psychology.

But further than that, it is very easy to see that Mr. Marshall's views are sound in relation to the two principal points made by him in the address spoken of: 1, that the doctors need the aid of the psychologist, and 2d, that the psychologist in return requires the help of the psychologically educated doctor.

The surgeon depends upon introspective comparison for the delicacy of touch that makes him successful, and the general practitioner must become an empirical psychologist, at least before he can correctly judge of the nature of his patient's ailments in that great mass of cases where disease is indicated only by changes of mental state in the patient.

Then, too, as we well know, there are a great many diseases that are indirectly aided by what are distinctly psychic means—by encouragement of the patient, for instance; and we cannot but feel that if the world of medical men had studied psychology more thoroughly, they would long since have shown us a *rationale* of the relief that is undoubtedly given, in some cases at least, by the methods adopted by the "Faith Curist," the "Christian Scientist," and the less honest men who use kindred means in their practice.

That the psychologist needs the help of the educated doctor of medicine is not questioned, and that he is gaining much help from this source is evidenced in the fact that many of our best psychologists, men like Professor James, of Harvard, have themselves been practical workers in the medical schools before they have attained fame as psychologists.

We quite agree that it is most wise for the student of medicine to make very considerable excursions into the field of psychology; nay, more than that, we feel that it would be a great advantage if, in all our medical schools, opportunities for the study of psychology were offered to the students. Still we are not quite prepared to follow Mr. Marshall in his view, that it would be well, here and now, to make a thorough knowledge of the principles of psychology necessary to the attainment of the M.D. degree; this is a matter that would involve serious consideration. The subject is so important, however, that it seems to us worthy of thought; and perhaps the time may come at no late day when the step suggested will appear to be wise, for we feel sure that if doctors knew more of the principles of modern psychology they would be better reasoners and better able to deal with the problems of errant human nature.

Facts for the Society for Psychical Research.—Lovers of the marvellous have the opportunity of finding a strange coincidence in a story recently told at the coroner's court in Birmingham. A girl aged thirteen disappeared from her home; her disposition was taciturn and sulky, which, coupled with her expressed apprehension of water, led to the worst fears being entertained by her parents. Her body was subsequently found in the canal. The aunt of the deceased, hearing that the girl was missing, dreamt that she was walking along the bank of the canal, and while looking into the water saw the face of her niece. The police were asked to drag the canal at the spot indicated in the dream; they did so, and at once found the body. Such was the simple story told at the inquest, a statement which if made in a novel would be ascribed to the powers of the writer's imagination.—*Lancet.*

THE CITY'S INSANE.

At the time of present writing the Mayor has not decided whether or not he will approve the bill transferring the care of this city's insane to the State.

Whatever be the result, we have no doubt that it will end in an improvement in the management of our Island institutions. If these remain with the city, our officials will have every inducement, as they already have larger means, for efficient care of the asylums. If the institutions go to the State, the State officials will also feel spurred up by recent criticisms to do their best.

The daily press has, with hardly an exception, criticised the honesty, wisdom, patriotism, and intelligence of the legislators at Albany. Every year the same picture of petty squabbling, political jobbery, and partisan strife is presented to us.

Some of these papers, however, are now urging that the responsibilities, and the opportunities offered by the care of over six thousand insane, with its necessary immense expenditure of money, be turned over to the tender mercies of this legislature. It is from a distrust in the capacity and honesty of this body that we have opposed such transfer. The present State system has accomplished much good, but it has not escaped much severe and very just criticism. And it would not follow that because State care succeeded with half a dozen asylums of moderate size, situated in the country or in small cities, that it would succeed in the care of institutions containing six thousand patients (over one-third of the insane of the State) in the midst of a great city. It has seemed to us that some of those who have so earnestly worked for the betterment of the insane, have accepted the formula of "State care" with an enthusiasm more fanatical than just, and have made it part of their faith that State care must necessarily remedy all our ills. But the economic and medical problems are quite different at Willard, Poughkeepsie, or Middletown, compared with those at Ward's Island.

With the increased intelligence of our people we feel sure that the insane will get better care under either State or City management, but we have an abiding faith in the doctrines of home rule and local government, and we have much confidence in the capacity of New York City to govern itself, badly as it has been betrayed in the past.

AN INQUIRY INTO THE EFFICACY OF THE "GOLD-CURE."

Rev. Dr. Buckley, the learned editor of the *Christian Advocate*, has made a serious attempt to investigate the therapeutic value of the so-called "gold-cure." He sent out letters of inquiry to a large number of physicians and clergymen. He got answers from 25 of the former and 68 of the latter, or 93 in all. Through these he obtained reports of 534 cases of inebriety treated by the "gold-cure," of which number 275 remained cured and 251 relapsed. This gives a proportion of cures of 51½ per cent. It might be said at once that if fifty per cent. are cured, something is accomplished; but the answer is that this same result can be secured by ordinary measures not involving the resort to secret preparations. Of one hundred drunkards who deliberately and honestly desire to break up their habits, surely over half will be rescued by measures known to the profession. As two-thirds of Dr. Buckley's correspondents were clergymen, and many of these were believers in the treatment, the percentage of cures obtained by the inquiry is probably too high. Even admitting it to be as high as fifty, the validity of the claim that the "gold-cure" is a specific, is surely disposed of.

News of the Week.

Office Thief.—Another office thief who came to wait for the doctor, has been caught with sixty dollars worth of surgical instruments in his possession. The prevention lies in the rule never to allow strangers to remain alone in offices containing valuables.

Riotous School Children.—The Board of Health of Seattle, Wash., ordered the closing of two schools the other day on account of the prevalence of scarlet fever. The principal of one of the schools refused to obey the order of the Board, and told the pupils to enter, despite the presence of the health officers. A wild scene followed, the four hundred or five hundred children entering at the doors and windows, some of them throwing stones at the officers and others getting out the hose and turning a stream upon them. It was not until noon that order was restored by the arrest of the principal, and the removal of the children from the building. A somewhat less exciting time occurred at the other school, the principal of which was also arrested for resisting the order.

The Texas State Medical Society.—At the annual meeting of this Society, held at Dallas on April 23d to 27th, Dr. P. C. Coleman, of Colorado, was elected *President*, Drs. Wagley, Kennedy, and Bass, *Vice-Presidents*, and Dr. H. A. West, of Galveston, *Secretary*. The next meeting will be held at Fort Worth on the fourth Tuesday in April, 1896.

The Alabama Medical Association, at the meeting held in Mobile on April 16th to 19th, elected Drs. William Henry Johnston, of Birmingham, *President*, and Dr. J. R. Jordan, of Montgomery, *Secretary*. The next meeting will be held in Montgomery, on the third Tuesday in April, 1896.

The School of Pharmacy of the Northwestern University of Chicago, has added to its faculty Messrs. Henry Kraemer and J. B. Nagelvoort.

Yellow Fever in Cuba.—Surgeon-General Wyman, of the United States Marine Hospital Service, has returned from a tour in the South, which was extended as far as Havana, Cuba. He reports that yellow fever is quite prevalent on the island, especially about Santiago. Dr. Wyman personally visited several of the United States quarantine stations along the Gulf of Mexico and along the Atlantic coast north of Florida. Arrangements were perfected all along the seaboard as far as possible for a rigid enforcement of the United States quarantine regulations, and he hopes that yellow fever may be kept out of the United States this spring and summer.

Another Typhoid Epidemic.—The papers state that there is a serious epidemic of typhoid fever in Watertown, N. Y., where there were, on the 11th inst., one hundred and fifty cases of the disease. "Eleven students of the high school are critically ill, and one death has occurred." The cause of this outbreak is believed to have been the pollution of the water-supply, "which is pumped from Black River at a point just below where two cemeteries drain into it," and that other epidemics in Watertown "during the past two years" are supposed to have been caused by the contamination of the water.

The Health Board as an Advertising Agency.—We have received so many protests from physicians here and elsewhere against the practice on the part of the State and City Health officials of endorsing proprietary medicines that we beg to call the attention of the gentlemen concerned to the obvious impropriety of so doing. At best it is a grave error of judgment, and should be remedied by withdrawing the "published by permission" clause in these circulars. One physician significantly writes: "The inquiry naturally suggests itself, why are these gentlemen so interested in the company that they are willing to prostitute their high offices to the degrading service of officially advertising its goods?" The answer is on the face of the circular "published by permission." I venture to say the "Board of Health of the State of New York" and the "Board of Pharmacy of the City of New York" are the only similar bodies in the United States which allow their highest officials to commit such flagrant acts without the severest censure.

The Cause of Baldness in Man is said by Dr. Leslie Phillips to be the fact that he cuts his hair. He says: "In men the hair is habitually cut short from childhood, while in women the converse is almost universally true. In boyhood and manhood, by clipping or cutting the hair, we remove the gentle traction on the bulb and follicle which the natural weight of the hair exercises, and which constitutes the essential and natural stimulus necessary to secure due innervation and vascular supply to the hair-producing structures. Loss of vigor, and finally more or less pronounced atrophy, is the inexorable result, modified or delayed, it may be, by collateral circumstances, predispositions, or conditions." Dr. Phillips warns the "new woman" against wearing her hair short. Almost every theory has some defect, and we might ask Dr. Phillips why men who clip their beard or shave for a long time do not get bald on their chins?

Before and After the Bath.—According to the *Mercredi Médical*, Max Edel, a German bacteriologist, took a bath, and then examined the water for microbes. He found it contained five billions eight hundred and fifty million micro-organisms. After a bath of one foot only, he estimated the number of microbes at one hundred and eighty millions. The question now arises, When did Dr. Edel have his previous bath?

Society and Association Meetings.—The American Neurological Association will meet in Boston on June 5th, 6th, and 7th.—The Association of American Physicians will hold its Tenth Annual Meeting in Washington, D.C., May 30th, 31st, and June 1st.—The North Carolina Medical Society held its Forty-second Annual Meeting in Goldsboro, on May 14th, 15th, and 16th.—The New Hampshire Medical Society will hold its One Hundred and Fourth Anniversary Meeting at Concord on Monday and Tuesday, June 3d and 4th. Dr. David P. Goodhue, of Springfield, is president, and Dr. Granville P. Conn, of Concord, is secretary.—The Queens County (N. Y.) Medical Society will hold its Anniversary Meeting at Mineola, L. I., on Tuesday, May 28th.—The New York State Medical Association will hold the Eleventh Annual Meeting of the fifth district branch in Brooklyn on Tuesday, May 28th.

National Association of Railway Surgeons.—Dr. John B. Murphy, of Chicago, at the National Association of Railway Surgeons, recently held in Chicago, was elected President of the National Association of Railway Surgeons.

Antitoxin.—In Dr. Louis Fischer's remarks before the Pediatric Section of the American Medical Associationthe words "Aronson's serum" should be substituted for "Behring's serum."

The Deutsche Policlinik celebrated its thirteenth anniversary by a banquet at Liederkranz Hall on Wednesday evening. Dr. C. Beck presided, and addresses were made by different members of the faculty and invited guests.

The New Private Hospital for Contagious Diseases.—The necessary amount of money having been subscribed, the work on the new hospital for contagious diseases will be commenced within a few weeks, and it will probably be ready for occupancy late in the autumn. The site will be at the foot of East Sixteenth Street. There will be three separate constructions—a central administration building and two ward pavilions—controlled by a board of governors, of which the President of the Health Board and the Medical Commissioners will be ex-officio members, and nine other members as follows: Dr. John W. Brannan, F. A. Schemerhorn, Paul Tuckerman, James J. Higginson, F. De P. Foster, Cleveland Dodge, Drs. A. H. Doty and T. Mitchell Prudden, and George F. Crane.

The American Surgical Association will hold its annual meeting May 28th, 29th, and 30th at the New York Academy of Medicine. The programme comprises a discussion On the Radical Cure of Hernia and papers on "Castration for Hypertrophied Prostate," "Operative Treatment of Cancer in Different Localities," "Present Status of Anæsthesia," "Restoration of Joint Function After Fracture," "Bacteriological Aspects of Pus and Suppuration," "Gun-shot Wounds of the Heart," "Injuries to Pneumogastric and Phrenic Nerves," "Dislocation of Ulnar Nerve at Elbow," "Ligature of Innominate Artery," "Suture of Gall-bladder and Duct," "Personal Experience with Mad Dogs," "Hernia of the Bladder," "Ligature of Spermatic Cord," and "Excision of Œsophageal Pouch." Clinics will also be held during Wednesday and Thursday afternoons at the different hospitals. The members of the medical profession are cordially invited to attend.

Obituary.

MORRIS H. HENRY, M.D.,

NEW YORK.

Dr. Morris Henry Henry died at his residence in this city, May 19th, of chronic nephritis of sixteen years' duration. He travelled much in search of health, but never gave up practice entirely, although for the past four or five years he had been a confirmed invalid. On May 2d, when driving, he was seized with an attack of angina pectoris, and it was with difficulty that he was got home and to bed. Since then he had grown worse, and from May 17th last he lay in a semi-comatose state until he died. Dr. Henry was born in London in 1835. He studied at the Polytechnic School at Brussels, afterward studying art in the Government school at Somerset House in London. He came to this country when he was seventeen years of age, and was graduated in medicine at the University of Vermont in 1860. He was an assistant surgeon in the navy during the war, and served under Farragut. After the war he came to New York. Governor Dix appointed him Surgeon-in-chief to the Emigrant Hospital at Ward's Island, where he served from 1872 until 1880. He was for a number of years Chief Examining Surgeon to the Police Department. He was a prolific and fluent writer, and originated and for five years edited the *American Journal of Dermatology*. He was the inventor of several appliances that have been widely adopted. Among them are the application of the plano-convex lens in examining the throat and upper air-passages; cutting-forceps for the removal of plaster-dressings; depilating forceps, and cartilage scissors, to facilitate the removal of dense tissues. He published monographs on various diseases, in which he was recognized as an authority. In 1876 he received the honorary degree of Master of Arts from the University of Vermont. He was noted for his opposition to quackery and his endeavors to raise the standard of the medical profession. He received in 1885, with the approval of Chief-Justice Waite, the degree of LL.D. from the University of North Carolina. His skill while surgeon in the Emigrant Hospitals, and his improved methods of treating certain diseases of the veins, won for him recognition from foreign countries. He was a member of many medical and surgical societies. He was also a member of the Union Club. As a speaker he always commanded attention and won for himself the reputation of a forcible and intrepid debater on all subjects of medical reform.

Dr. Henry was a member of the University of Athens, and was decorated by the King of Greece and by the Sultan—by the latter with the Imperial Order of Medjidie. His first wife was a daughter of Hugh Hastings, of the *Commercial Advertiser*, and by her he had a son, Hugh Hastings Henry, who is now a corporal in the army, stationed at David's Island. Dr. Henry's second wife survives him. His father was a celebrated Oriental scholar. His godfather was Sir Moses Montefiore.

MR. ARTHUR DURHAM,

LONDON, ENGLAND.

Mr. Arthur Durham, Consulting Surgeon of Guy's Hospital, expired on Tuesday from acute pneumonia. He was born in Northampton in 1834, but entered Guy's in 1855, and passed through all the stages to consulting rank. He was admired and esteemed as a teacher, and greatly trusted as a surgeon. Full of enthusiasm and kindly sympathy he was a charming friend and general favorite. His contributions to surgery are well known to our readers. He was to have given the surgical address at the coming meeting of the British Medical Association—a great treat to the audience—but alas, his pleasant voice will be heard no more.

SIR GEORGE BUCHANAN, F.R.S.,

LONDON, ENGLAND.

Sir George Buchanan died on Sunday last, aged eighty-four. It is only about three years since he resigned his position as medical officer of the Local Government Board, after which he was appointed chairman of the Royal Commission on Tuberculosis. For about forty years his name has been connected with sanitary administration. He became chief of the department in 1879 and retired in 1892, when a knighthood was conferred upon him. He carried into his retirement the good wishes of the profession and of all who know anything of the history of English sanitary improvements.

Obituary Notes.—Dr. George A. Perkins, one of the best known physicians in Massachusetts, died on May 18th, aged eighty-one. He was born in Salem October 15, 1813, and received his elementary education in private schools. In 1833 he went to Africa as an Episcopal missionary, but two years later returned to America, entered Harvard College, and studied medicine. Soon after graduating he returned to Fishtown, West Africa, as a medical missionary, but in 1850 returned to Salem and began the practice of medicine. He was Post Surgeon at Ports Lee and Pickering from December, 1863, to May, 1865, and for a long time physician at the Salem House of Correction and the almshouse. He was widely known as an expert microscopist and chemist. He was a member of the original staff of the Salem Hospital. He leaves two daughters.—Dr. Henry J. Hesse, one of the prominent physicians of Brooklyn, died at his home on May 20th, from pneumonia, which he contracted two weeks ago. Dr. Hesse was born in 1853 in Brooklyn, and studied medicine and was graduated from the Long Island College Hospital in 1876. He was one of the founders of St. Catharine's Hospital, and for years was President of its Board of Physicians and Surgeons. He entered politics in 1885, and in the fall of that year was elected Coroner of the Eastern District.—Dr. Harlan P. Allen, of Columbus, O., died at Roosevelt Hospital on May 2d of suppurative appendicitis. Dr. Allen was one of the leading oculists and aurists in Columbus. He was born in Springfield, Mass., in 1856.—Professor Emil Noeggerath died on May 3d, at his home in Wiesbaden after a long and painful illness.

The Late Dr. Bernard E. Vaughan.—At a stated meeting of the Hospital Graduates' Club held April 23, 1895, the following resolution was adopted:

'The Hospital Graduates' Club desires to place upon its records, its deep sense of the loss it has sustained in the death of its late member, Dr. Bernard E. Vaughan. From the date of his admission to the club to that of his decease it had no warmer friend or more loyal supporter than he. He was faithful in his attendance, cordial in his social relations, and able in his scientific work. By his death, the members of the club feel that they have lost a valued friend, and the medical profession of the city one of the most promising of the younger men in its ranks. Be it therefore,

Resolved, That the sincere sympathy of the club be extended to his bereaved family, and that this action be entered upon the club records and published in the professional journals of the city.

James E. Newcomb, M.D.,
Thomas S. Southworth, M.D.,
Committee.

Reviews and Notices.

Clinical Drawings. A Collection of Representations of the Changes of the External Form of the Body Occurring in Internal Diseases. By H. Curshmann, Professor in Leipzig Klinische Abbildungen Summenny von Darstellungen der Veränderung der aüsseren Körperform bei inneren Krankheiten. Berlin, 1894.

It is no longer necessary to emphasize the important part photography has begun to play in the modern study and teaching of medicine. What the author of this work has aimed at he has fully accomplished. Not only does he offer a large number of rare anomalies, but the different stages and characteristic positions and motions of the patients are represented with uncommon accuracy. Every one of the plates is a masterpiece, and the accompanying texts are models of precise and concise description. We have no doubt of the entire adaptability of the handsome book both to the profession and to teachers of medicine, and trust the author will keep his promise of continuing his work in the same style.

Not the least interesting among the cases of muscular dystrophy (progressive infantile, pseudo-hypertrophic, lipomatous, etc.) is Plate 12. It represents an enormous bilateral and uniform hypertrophy of the muscles of the arms and trunk, those of the lower extremities being normal. The anomaly was found in a professional athlete of thirty-eight years, of healthy extraction, with marked neurasthenia, and, while the electrical excitability of the muscles was unchanged, with considerable diminution in strength of all the muscles of the extremities. The nervous system is amply represented in the beautiful collection of cases; syringomyely, poliomyelitis, and polio-encephalitis, paralysis agitans, athetosis, catalepsy, local paralyses (infraspinatus, serratus, facial), and Graves's disease are successfully treated both in text and picture. No less striking are the drawings and descriptions of aneurisms, of sarcoma and carcinoma, of congenital fissure of the sternum, of Hodgkins's disease, of akromegaly, etc.

A Course of Elementary Practical Bacteriology. By A. A. Kanthack, M.D., and J. H. Drysdale, M.B. London and New York: Macmillan & Co. 1895.

The work is divided into Lessons, and is arranged in three parts: I. General Bacteriology; II. Bacteriological Analysis; III. Bacteriological Chemistry. It is intended for laboratory work. The third part of this book forms, so to speak, an appendix to the two previous parts, and comprises an introduction to Bacteriological Chemistry for those who are desirous of devoting some of their time to advanced investigation and research work. It is written in a concise form, and will prove useful to every practitioner.

A Manual of Genito-Urinary and Venereal Diseases. By Bukk G. Carleton, M.D., Professor of Genito-Urinary Diseases, Metropolitan Post-Graduate School of Medicine, etc. With Venereal Diseases of the Eye by Charles Deady, M.D., Professor of Ophthalmology and Otology, College of New York Ophthalmic Hospital, and Vesical Calculus and External Urethrotomy, by William Francis Honan, M.D., Adjunct Professor of Genito-Urinary Diseases, Metropolitan Post-Graduate School of Medicine. 8vo. New York: Boericke, Runyon & Ernesty. 1895. Pp. 315.

This very compact, well-written book is mainly from the Homœopathic standpoint, and gives a very clear picture of the clinical phenomena noticed in connection with the different features. As might be anticipated, there are many adaptations of special remedies for special symptoms which will doubtless be appreciated by those for whom the work is more particularly written. The surgical procedures and manipulations are up to date, and all the essential surgical appliances and methods are given in sufficient detail.

A Book of Detachable Diet Lists, and A Sick-Room Dietary. By Jerome B. Thomas, M.D. Philadelphia: W. B. Saunders. 1895.

This book contains a collection of Diet Lists for Albuminuria, Anæmia and Debility, Constipation, Diabetes, Diarrhœa, Dyspepsia, Fevers, Gout or Uric-acid Diathesis, Obesity and Tuberculosis, and will prove useful and practical in many ways.

Manual of Chemistry. A Guide to Lectures and Laboratory Work for Beginners in Chemistry. A Text-book Specially Adapted for Students of Medicine, Pharmacy, and Dentistry. By W. Simon, Ph.D., M.D., Professor of Chemistry in the College of Physicians and Surgeons of Baltimore, in the Maryland College of Pharmacy, and in the Baltimore College of Dentistry. Fifth Edition, thoroughly Revised, with Forty-four Illustrations and Eight Colored Plates Representing Sixty-four Chemical Reactions. Philadelphia: Lea, Brothers & Co. 1895.

The general plan of this edition is the same as that of the fourth, which we reviewed some two years ago, although the constant advance of chemical science has necessitated a number of additions, and some changes have also been made to bring the work into harmony with the new United States Pharmacopœia.

Beginning with an exposition of the general laws of matter as bearing upon chemical phenomena, the author treats successively of inorganic, analytical, organic, and physiological chemistry. Numerous colored plates depict the reactions of the more important medicinal salts and alkaloids and also some of the urinary tests. The author's practical experience as a teacher has taught him very clearly what is needed in the way of chemical instruction by students of medicine, and he has well availed himself of this knowledge in writing the present work.

Surgical Pathology and Therapeutics. By John Collins Warren, M.D., Professor of Surgery in Harvard University; Surgeon to the Massachusetts General Hospital. 8vo, pp. 832. Philadelphia: W. B. Saunders. 1895.

The long experience of Professor Warren as a teacher and his extensive practice in a large hospital eminently fit him for a proper performance of a task requiring careful study, breadth of view, and the practical application of broad scientific principles. Such a work as the one before us has, in view of recent surgical advances, become a necessity, and we are happy to say that in reference to many of its excellences as a practical guide in the estimation of the application of pathological principles to clinical phenomena, it is unique.

The importance of studying these relations cannot be questioned. If any doubt existed regarding this point the book itself would be an unanswerable vindication. It is the demonstration of the reason why that impresses the fact and gives every study the proper turn of practical utility. The author very properly intimates that the subjects treated in the present volume are seldom grouped together in text-books, and we can add are still less frequently discussed in a clearly scientific manner as in the present instance. The subject of bacteriology very properly takes a leading place not only in the introduction of the principles upon which modern surgery is founded, but in the explanation of the different symptoms and lesions presented in given pathological conditions. The description of the various forms of bacteria, their illustration in admirable chromolithographs, and the manner and methods of their propagation are intelligently and interestingly given. The

pathology of fevers, the relations of phenomena to lesions and the rationale of pathological conditions connected are presented in an exhaustive manner. Under this heading we have classified, simple fever, or the fever of repair, the fever of inflammation, connected with microbic influences, and the fever of pyæmia.

Very many interesting points bearing on the pathology of inflammation are given in exhaustive chapters on the subject. Erysipelas, Hospital Gangrene, Tetanus, Hydrophobia, Actinomycosis, Anthrax, Glanders, and Snake-bite also receive proper attention in the same lines of study. The article on hospital gangrene, considering the present rarity of the disease, is particularly full. It is, in fact, the best account of this disease that has appeared since the late war. More important than that of any of the former diseases is the consideration of tuberculosis in its various surgical bearings. Carcinomatous and other growths are quite exhaustively discussed, and the microscopical and other illustrations of different specimens are in keeping with those of others scattered throughout the work. The bacteriological bearings of aseptic and antiseptic surgery are presented in a thoroughly practical way which will be especially appreciated by the progressive surgeon and the alert practitioner. Articles bearing on blood-serum therapy and the technique of toxine preparations conclude this admirable work. Evidently prepared with great care, and abounding in exhaustive scientific data, its still greater recommendation rests upon the clear and skilful manner in which the author adapts such knowledge to the practical needs of the progressive student.

Seventeenth Annual Report of the State Board of Health of the State of Connecticut, with the Registration Report for 1893 Relating to Births, Marriages, Deaths, and Divorces. New Haven: The Tuttle, Morehouse, & Taylor Press. 1895.

Among other interesting matter in this volume is a report of the outbreak of typhoid fever at the Wesleyan University, caused by the eating of contaminated oysters at a fraternity supper. There is a list of the registered practitioners of the State, among whom we find nearly one hundred residents of other States, half of them from New York City, and most of them registered at Greenwich.

Eighth Annual Report of the Managers of the St. Lawrence State Hospital, for the Year 1894. Albany: James B. Lyon, State Printer. 1895.

This volume contains a number of interesting clinical reports illustrated by well-executed colored plates.

Diseases of the Heart and Arteries. Their Causes, Nature, and Treatment. By John H. Clarke, M.D., C.M. Edin., Extraordinary Member of the Royal Medical Society of Edinburgh; Fellow of the British Homœpathic Society; Physician to the London Homœpathic Hospital. London: E. Gould & Son. 1895.

It is curious to read a work on diseases of the heart in which no account whatever is taken of pathology and little of diagnosis, the author's concern being only of the symptoms and of the drug which will cause their subsidence. Such is the book before us. It is for the greater part a report of cases in which symptoms suggesting diseases of the heart or of the arteries were present. There is a chapter on treatment in which some very sensible suggestions relating to diet and hygiene are given. The author gives a list of drugs which he regards as indispensable if one would be prepared for the cure of all cases of cardiac trouble. There are fifty-five of them, taking in the whole alphabet from aconite to veratrum viride. We really do not see, after reading a number of the cases reported here, that the author has any greater success in the relief of cardiac symptoms with his fifty-five drugs than most practitioners obtain with aconite, digitalis, caffeine, and three or four other cardiac remedies.

A Manual of Bandaging. Adapted for Self-instruction. By C. Henri Leonard, A.M., M.D., Professor of the Medical and Surgical Diseases of Women and Clinical Gynecology, in the Detroit College of Medicine. Sixth Edition, with 139 Engravings. Detroit: The Illustrated Medical Journal Co., Publishers. 1895.

This appears to be a useful book on bandaging and one that would be of great service to the student or young graduate who has not had the advantage of practical experience in hospital or dispensary. The instruction here given might also not come amiss as a refresher of the memory to many an older practitioner whose hand has lost its cunning through want of practice in surgical dressings. The work is profusely illustrated by simple cuts designed more for clearness than for beauty.

How to Become Registered. Designed as a Substitute for Professors and Instructors, when these Important Adjuncts of Pharmaceutical Study are Beyond the Reach of the Student. By Harry B. Mason, Ph. G., North Granville, N. Y. Published by the Author. 1895.

This is a little manual containing directions for self-instruction in pharmacy for those who are unable to attend college lectures.

Index of Medicine. A Manual for the Use of Senior Students and Others. By Seymour Taylor, M.D., M.R.C.P., Senior Assistant Physician to the West London Hospital. Philadelphia: Lea Brothers & Co. 1894.

Although called an "index," the subjects treated of in this work are not arranged alphabetically but logically according to systems. The descriptions are of necessity very brief, but they are at the same time clear and comprehensive, and for a short definition of any special disease or for a useful hint as to the therapeutic management of a troublesome case the work seems to be well adapted. There are occasional diagrams explanatory of the genesis of certain symptoms in special diseases of the liver, heart, nervous system, etc., which are suggestive and helpful. We do not, as a rule, approve of summaries of this sort, but we must admit that the one before us is excellent of its kind.

Die Infections-Krankheiten, ihre Entstehung, ihr Wesen und ihre Bekämpfung. Für Aerzte and Verwaltungs-Beamte. Von Dr. W. Plange, Kgl. Kreisphysicus. Berlin: S. Karger. 1894.

The author of this little work was led to write it by what he observed, during his service as district physician, of the popular ignorance, even among the officials, in matters relating to hygiene and the prophylaxis of contagious diseases. The book is aimed not only to aid the physician in his struggle against disease, but also to teach him how to inculcate in others a due regard for the primary rules of hygiene and a mode of living that will best tend to fortify them against the attacks of infectious diseases. The book is interesting and instructive.

Grundriss der Histologie. Für Studierende und Aerzte. Von Dr. Bernhard Rawitz, Privatdozenten an der Universität, Berlin. Mit 204 Abbildungen. Berlin: S. Karger. 1894.

This is a comprehensive and satisfactory guide for the student of histology, written by one whose daily work it is to teach this fascinating science. The illustrations are somewhat schematic, but, for that very reason, clear and helpful. One who will use this book as a help in microscopical work cannot fail to make progress, even without a teacher's aid.

Society Reports.

American Medical Association.

Forty-sixth Annual Meeting, held in Baltimore, May 7, 8, 9, and 10, 1895.

SECTION ON DISEASES OF CHILDREN.

SECOND DAY, WEDNESDAY, MAY 8TH.

(Continued from page 638.)

Etiology of Infantile Summer Diarrhœa.—DR. ROSA ENGELMANN, of Chicago, sent a paper with this title, which was read, in the absence of the author, by DR. KOPLIK. The disease resolves itself into intestinal intoxication through the action of bacteriological organisms. These germs are proved to be of very numerous kinds. Accumulation and absorption of the products of these infections and their ptomaïnes produce the local lesions and the systemic effects—ento-colitis, pneumonia, meningitis, et cetera. Various kinds of organisms have been found. Future investigations will probably show the relation of these various organisms to the special conditions produced. Observers have pointed out that the disease is localized in some epidemics, while the germs remain confined to the intestines, and that grave systemic symptoms only follow after the micro-organisms have entered the circulation.

Colitis in Infancy and Childhood.—DR. EDWARD ANDERSON, of Brockville, Md., read a paper with this title. The disease prevails in hot weather, due to intestinal fermentation, to which hot weather is conducive. This is made more liable to occur by impaired health, especially so in artificially-fed children, as is well known. Undigested material accumulated in the intestine conduces to the development of the disease, which should be eliminated by cathartics or washed out by injections. Cases illustrating the management employed by the author were read. He insists upon the giving of mercury and enemas. Change of diet should be carefully made. Mercury is the drug advocated. Blue mass should be administered until symptoms abate, together with warm-water injections.

Membranous Enteritis Associated with Ascaris Lumbricoides.—DR. IRVING M. SNOW, of Buffalo, N. Y., read this paper. He introduced the subject by citing a case in which casts of the intestinal membranes were discharged, during the course of the disease, three inches long, and cylindrical, on the first occasion. After this several smaller portions of membrane were discharged on several occasions. Finally ascarides were discharged. Calomel and santornin then brought away two more. Later others were brought away. The casts ceased to be discharged after the worms were got rid of. The history of this case is peculiar. The casts evacuated were accompanied by blood and mucus, but, contrary to the usual case, there was no pain nor tenesmus or other uncomfortable symptom. A similar case was read, reported by another observer. In this case, fourteen days after discharge of fibrous membranes ascarides were passed.

Magnesium Sulphate in the Treatment of Diarrhœa in Children.—DR. STEWART PATTERSON, of Pittsburgh, read this paper. The disease has been shown to be due to accumulation of morbid germs and resulting accumulations. Abnormal chemical action set up by organisms would appear to be an important factor; the contents of the stomach and intestines being rendered acid during the earlier stage of the disease. The remedy under consideration corrects the acidity and expels the contents of the stomach and intestines. One drachm a dose, or more, before meals, is given. Reports of the duration of the disease treated at the dispensary were given, showing the efficacy of the treatment. Beneficial results are claimed by the author in nearly all cases.

DR. KOPLIK, of New York, said that meningitis and pneumonia in ento-colitis are due directly to the contamination of the blood by micro-organisms and their products. As to the use of mercury in intestinal inflammation, great care is desirable, due to the danger of inducing thereby kidney complications, entire suppression of urine being readily induced in these cases by mercury. As to the use of sulphate of magnesium, the speaker would say that he preferred to use very little medicine, and to rely on regulation of diet—starving will cure many cases and is borne better than might be expected—white of eggs, and water and broths as diet were among his favorites. Bismuth he employed to a large extent.

DR. W. D. BOOKER, of Baltimore, said that probably the bacteria weakened the cell action of the intestine. We do not know altogether what takes place to cause all the various conditions. Hot weather, we know, favors the growth of organisms and they seem to thrive on milk particularly. When there is a weakened condition the bacteria have an opportunity to get in their work. Bad management of diet conduces to this condition. The regulation of diet is, therefore, of the first importance. The lesions produced from the toxins of the intestines act on the organs very much like those produced by infectious diseases, such as diphtheria. The bacteria are easily traced through the various tissues of the intestine and leave traces in suppuration. His own observations show no uniformity of pathological conditions, indicating a mixed or varying infection. No two cases are ever alike. One class, clinically, shows nervous symptoms. Another class of serious cases shows more local effects on the mucous membrane of the intestine. As to treatment, the speaker regards the dietetic as the first consideration. Stop the food the child is taking and then get rid of the contents of the intestines. Substitute some water-gruel. Calomel is the one remedy the speaker relies on. There is some action from small and frequent doses of calomel on the mucous membrane which we do not yet understand. One-sixth grain every hour for a number of doses. We cannot expect to effect disinfection by drugs, but must rely on getting rid of accumulations and restoring the normal condition of the mucous membrane. After the disease has gone on for a week or more, medicine ceases to be effective, and diet is about the only measure to be relied upon. Bismuth is often disappointing. Irrigation sometimes gives relief, but where there is a great deal of inflammation present it must be used cautiously. The irrigation should be done with a soft catheter and two or three quarts of water used and allowed to run out as it will by return current.

DR. RIGGS said that he believed that other factors than bacteriological entered into the cause of diarrhœa. We do not discriminate, as a rule, the different conditions. Where there is gastro-enteritis with watery discharges, after the accumulations are removed, there is nothing so effective as the nitrate of silver. It will stop the vomiting and the watery discharge. When the lower bowel is affected then mercury is the best remedy. Another speaker said that sending children on the water for trips of a day or two will produce beneficial effects. It would seem in these cases that the change for the better was due to removal from the heat of the city, therefore there was evidently something more than bacteria present as a cause. The practice of using purgatives and irrigating should be made conditional as to whether there is anything to get rid of. Often autopsies show very few bacteria, or anything else, in the intestine. In those cases in which it is evident that the symptoms are due to the presence in the system of toxins then opium is indicated. In many cases opium has been found by the speaker beneficial after everything else had failed. Another speaker objected to

sulphate of magnesia on account of its horrible taste. Something less nauseous could easily be found of equal efficiency. He has used hot water and calomel; when pain is present morphia and atropia.

Dr. Fischer said that the routine treatment of diarrhœa in Germany is washing the stomach and intestine, as high up as possible, with a simple warm saline solution. When there is loss of water in the tissues hypodermatic injections are made. Salt is constipating. This is shown by the effects of salt air on those crossing the ocean.

Dr. Adams said his experience has shown that very much is accomplished by simply removing the child from the heat. He related his experience with hospital children removed from houses where they were very much crowded. Fifty per cent. of these children died, and there were no commensurate lesions found at autopsies. It was very hot weather. There was, on an average, less than ten stools a day in these cases. There may have been drain contamination, possibly, but the speaker believes the heat was the most potent factor. In irrigating provision should be made for the return current, to get the best effects.

Dr. Adams related several severe cases where removal from heated air to the cool of the mountains, without medicine, had promptly cured the diarrhœa.

Dr. Anderson, in rebuttal, said he could not always take his patient to cooler climates. He spoke of the impossibility of sulphate of magnesia in cases of severe vomiting. Calomel or gray powder was the only feasible remedy to unload the bowels in many cases.

Dr. Patterson, in rebuttal, said he did not want to be understood as an advocate of sulphate of magnesium as a cure for diarrhœa. He did advocate removal of the cause of the diarrhœa in some way. Sulphate of magnesia was one of the agents useful for this purpose.

Third Day, Thursday, May 9th.

Antitoxin in Scarlatina.—Dr. Clark Parker reported a case occurring in a child aged twenty-seven months. Made diagnosis on Saturday morning; eruption and all other ordinary symptoms present. Sunday it appeared more like diphtheria, but cultures afterward showed streptococci. Antitoxin was used and the symptoms abated under it promptly and the child did unusually well under the circumstances. The speaker thinks highly of antitoxin in scarlet fever and in mixed cases. He uses other treatment the same as when antitoxin is not used locally.

In the case reported above only a trace of albumin was found at any time. The desquamation was not so great as ordinarily. The speaker believes that this is due to the antitoxin modifying the severity. Answering the question the speaker said he used fluid antitoxin of the Pasteur Institute of Boston.

Treatment of Double Club Feet and Hands.—Dr. B. Merrill Ricketts, of Cincinnati, read a paper on this subject. He described the condition as affected by intrauterine influence. A case was described in which there was proved to be present multiple peripheral neuritis. The treatment was by plaster-of-Paris bandages, under which there had been much improvement in position of the feet, but the hands had not improved so much. The cause of the multiple neuritis the reader was unable to discover.

Dr. Thomas H. Manley, of New York, discussed the advisability of resorting to operative procedure, and said it was a mooted question which was the better method, that, or the mechanical. He said that the affection of the muscles causing deformity of the hand analogous to those causing that of the leg, was a very rare condition, if not unique.

Dr. Ricketts remarked that the hands did not improve so rapidly as the feet because, probably, of the aid to cure given to the feet by the weight of the body in walking and standing.

Tubercular Meningitis.—Dr. William E. Lockwood, of Baltimore, read a paper on this subject. The paper was based on cases of his own, in some of which autopsies had been made. Of the ten cases seven were under bad sanitary conditions. The usual contributary causes were present—bad air, poor diet, heredity, etc. He gave the results of the observations under several heads.

Family history: All showed hereditary vices, that is, the families did, save two which could not be determined. Residence and surroundings showed bad sanitary conditions in nearly all. Experiences in these cases showed him the necessity of study before making diagnosis in children, where fever and obscure symptoms were present.

Summary: Seven negroes and three whites. Six gave histories of hereditary tuberculosis. Average duration, four weeks. The pathological findings were read.

Tuberculosis and Infected Milk.—Dr. Frank S. Parsons, of Philadelphia, read a paper entitled "Has Tuberculous Cow's Milk Causative Influence in Tuberculous Lesions of Infancy?" Frequent traces of early tuberculosis in the lung of those dying late in life, which have healed, was referred to as possibly to be accounted for in some cases by early infection from milk. The danger is to those who furnish good soil for tuberculosis—the weak, and those predisposed by heredity. There is no danger from the milk of infected cows, unless the milk actually contains tubercle bacilli.

Diagnosis of Pneumonia in Children.—Dr. J. P. Crozer Griffiths, of Philadelphia, read a paper on this subject. A limited area of dulness is easily overlooked unless light percussion is employed—and even then, sometimes, there will be no dulness during the attack—sometimes the disease is diagnosed as existing on the wrong side, due to affected lung being obstructed as to air; while the unaffected lung performs the functions of both and is less resonant on percussion. Broncho-pneumonia may assimilate croupous pneumonia very closely in all the local symptoms. To illustrate this a case was related. Autopsy showed typical broncho-pneumonia in the case in which a diagnosis of croupous pneumonia had been made without any doubt of its truthfulness. It is liable to confusion with pleuritic effusion, as is well-known. A case was related illustrative of this in which the error was due to the absence of the ordinary symptoms of effusion, and those of broncho-pneumonia were present. These cases are very puzzling; often keep the attendant in a state of vacillation. Phthisis is particularly liable to cause confusion, being mistaken for broncho-pneumonia in the early stages, or broncho-pneumonia for it. The various features of this difficulty were pointed out by the history of cases. It may happen that broncho-pneumonia precedes the phthisis, as we know. How often this happens it is hard to determine.

The pain in pneumonia is sometimes referred by children to the abdomen—as was illustrated by a case. The case was admitted to the hospital with diagnosis of peritonitis, in which autopsy showed no peritonitis, but purulent broncho-pneumonia. A case was related in which an extensive pneumonia had been overlooked for several days, in which there had been no cough whatever to call attention to the lungs.

Dr. G. W. McNeill, of Pittsburg, said, regarding diagnosis of tuberculous meningitis, according to textbooks one would suppose this easy, but experience did not always prove it true, as in a case he related in which a positive diagnosis was made. The child recovered. This result convinced the speaker that he had been in error in his diagnosis, as he did not believe recovery ever took place in tubercular meningitis. Never in his own experience, where he could be sure of the diagnosis, at least.

Dr. Mulhouse, of Connecticut, said he had often

been unable to make a diagnosis until after the fifth day in pneumonia in children. Probably the disease began centrally. At any rate after about five days the diagnosis from physical signs became possible, when before it had been impossible. As to iodide of potash, he thought Dr. McNeill gave too little to produce any effect, if any can be produced by it in tubercular meningitis. As for himself, he thought nature did more than the iodide. He thought recovery was not to be expected in tubercular meningitis.

Another speaker asked Dr. McNeill if there had not been suspicion of syphilitic disease. The answer was "none whatever."

As to pneumonia, he thought the time for hopeful treatment was in the first stage. After this stage no effect could be expected to be made upon the disease itself. Symptomatic treatment was, after the first stage, with good nursing, all that would be of any use.

Antiphthisin in Tuberculosis in Children was the title of a paper by Dr. Edwin Klebs, of Asheville, N. C. The remedy can only be effective in those cases in which there are no secondary pathological products in the tissues. Properly selected cases—only uncomplicated cases—are therefore necessary to test the remedy. When this is done, and the remedy is properly prepared and administered, it is effective. In all tubercular and scrofulous cases in which suppuration has not yet taken place the treatment is applicable. It is known that tuberculosis may lay for a long time latent to develop at last into active symptoms. But all debilitated patients are not to be regarded as tubercular; but where there is any evidence of scrofula, they should be so regarded.

The effect of antiphthisin was illustrated by cases. Two cases of well-developed phthisis of the lungs, in which all symptoms of the disease have disappeared under the use of the remedy, were related in full. Cases of scrofulosis were then related. The first, a girl with glandular enlargements of scrofula, and other symptoms in the eyes. The tuberculous deposits entirely disappeared under the injections. Its effect on tubercular joints was also illustrated by a successful case, all symptoms disappearing. This refers to the more superficial affections and not to the affections within the bone, where less satisfactory results were obtained.

Dr. Larrabee, of Louisville, Ky., spoke of tubercular meningitis, declaring that no one was competent to make a diagnosis who had not sat at least an hour at the bedside. Three points were to be made out clearly: the cerebral symptoms, the contracted abdomen, and the projectile vomiting. The knitting of the brows must be present beside the vomiting and contracted abdomen. The speaker said that we hardly appreciated the frequency of syphilitic inheritance. Referring to Dr. McNeill's case, he said he always thought when he got good results in such cases from iodide of potash he had uncovered the syphilitic diathesis, which he had before failed to discover. We now recognize pneumonia as a microbic disease. In children the brain symptoms vanish as the lung symptoms clearly come out. The bacterial infection has preceded for some time the full development of the lung symptoms.

Referring to Dr. Klebs's paper, he said that Koch's publication of tuberculin was premature and the results in consequence unfortunate, but that we should now take up the subject-matter again without prejudice. He recognizes in scrofula another inherited condition of vitiated growth, but not specific tuberculosis. The latter is not, properly, inherited, but the scrofulous condition is. A speaker asks if antiphthisin and tuberculin are the same, etc. Another asks if it may be given by the mouth successfully.

Dr. Griffiths, in rebuttal, says that he believes recovery is possible in tubercular meningitis, as was shown by an autopsy, where it was proved to have once existed. As to the hydrocephalic cry, it is not diagnostic of this disease. It is observed in various nervous and cerebral states.

Dr. Klebs remarked that distinctions between tuberculosis and scrofulosis had been clearly disproved. The cheesy glands are tuberculous, and when exploded and their contents disseminated in other tissues are capable of producing phthisis. When purely tubercular disease is present remarkable results are obtained with anti-tuberculin; but when there is mixed affection this is not so. As to the antiphthisin, it is only tuberculin in a purified form. It may, if administered in large doses, be dangerous in human beings. It is not advised to use it as a diagnostic agent; but it is efficacious as a test of the presence of tuberculosis, as we test the presence of syphilis by the use of iodides. As to tubercular meningitis, Dr. Klebs has had no experience with the remedy, save in one chronic case which recovered. He had always used the remedy for diagnosis when he was in doubt. This was said in answer to questions.

The Chairman announced that this would be the last session of the Section; that the papers appointed for Friday would be read to-day in place of several on the programme whose writers were not in attendance.

Bromoform in the Treatment of Pertussis was the title of a paper by Dr. P. J. Eaton, of Pittsburgh, which was read by the Secretary. It is a sedative, germicide, and antipyretic. Illustrative cases were given, in which prompt relief occurred and early recovery—some in ten days. In adults rapidly increasing doses, up to thirty drops a dose, were administered. One patient of three years who took half a drachm by mistake had symptoms of poisoning soon after—stupor, etc. The dose given to young children was from two drops up to six usually. The dose was begun with a small one, increased rapidly until tolerance was reached, then continued so long as needed, with gradual diminution as the symptoms subsided. Alcoholic solution of absolute purity should be used only. It has a sweet pungent taste when rightly prepared. We have in this remedy one by which the disease is controlled, ameliorated, and the mortality greatly reduced. Impure or overdose causes nausea and vomiting, followed by stupor. It may be given in capsule.

Infant Mortality.—Dr. A. J. Work, of Eckhart, Ind., read a paper on some of the causes of great mortality in infancy and childhood. The conditions in great cities, of crowding, poverty, and unsanitary circumstances, are well known. This great mortality is observed most particularly under the age of five years. Congenital weakness is evidently a potent factor, such a large percentage occurring soon after birth. Hereditary influences will be first considered. This factor affects population in the diminution of births as well as by mortality after birth. The affections inherited affect the constitution or special organs or parts of the body. Animals have higher instincts regarding proper food than human beings. The ignorance or indifference of mothers is very frequently observed to a degree scarcely credible. Attention to proper clothing is not sufficiently regarded. Flannels are often not used when they are so necessary to protection in babies. Zymotic disease is one of the great causes of death. Sanitation and isolation are coming to affect favorably this cause. The lack of natural affection, in these times so prevalent, like that to which St. Paul refers in the Epistle to St. Timothy, is a sad spectacle. What may we expect for future generations unless this indifference is abated? Infantile insurance was mentioned in this connection. The physician has a duty to perform here.

Modern Methods of Preparing Food for Infants.—Dr. W. D. Booker, of Baltimore, Md., read a paper on this subject. The small size and weak function of the young infant must be considered and the quantity rationally graded in accordance. The indications of overfeeding are regurgitation and indigestion as indicated in the stools.

The cow's milk should be made, as has been attempted, to assimilate artificially mother's milk. But this has not been altogether successfully done yet. Sterilization of milk in this connection is the most important advance in this direction, first introduced eight years ago. This takes into consideration the proper care and food of the cows, care of the milk after it leaves the dairy, as well as subsequent procedures. Germs have been found in the milk of cows after three hours in great number. This forms a serious obstacle to sterilization, not because the germs cannot be destroyed, but because of the changes they produce in the milk which render it objectionable. Proper care of the bottles should be observed. Lack of it is one of the most fertile sources of infection of the milk. This point has been carefully proved by experimenters. Care of the nipple of the bottle is also of great importance. Temperature of 103° C. is necessary for sterilization, as has been proved. Thus heating the milk does not impair its digestibility and nutritive qualities. His personal experience is quite extensive with sterilized milk and it concurs with others, as stated above. If the milk is fresh twice a day complete sterilization is not absolutely necessary. The milk must be boiled for fifteen minutes. Some have claimed that summer diarrhœa is not lessened by sterilized milk ; but the reader believes this is because of imperfect measures, and that when the practice becomes a well-established custom and all its minutiæ are generally attended to and carried out, the effects will become apparent. The separation of the casein from the milk of cows by centrifugal force, as practised in Boston, was referred to, whereby this ingredient and some of the fat are removed, so as to leave the constituents the same as those of mothers' milk. The objection to this method is its great expense, as at present practised. But the method is simple and will become inexpensive once adequate means are provided.

The Care of Infants and Children.—Dr. A. C. Cotton, of Chicago, read the paper. He said the subject which he proposed to discuss was old and homely—the best means to protect the infants placed in our care. The leading factor for evil in this regard is the daily neglect. This begins with the first moments of life. The practice at the Presbyterian Hospital at Chicago in caring for the new-born was related—washing the mouth, oiling, wrapping up, giving water, and everything else to make the baby comfortable. There is shock to the baby from the processes of birth, it should be remembered. The baby is not washed for several days, but frequently oiled. The infant suffers from intense thirst after birth, especially for two days, and should be given water frequently, slightly warmed. The baby should go to sleep soon and sleep most of the time for several days. The body is more thoroughly cleansed by wiping the body with absorbent cotton saturated with oil, and this avoids the irritating and drying effects upon the tender skin of washing with soap and water. Trial will dispel prejudice against this practice entertained by mothers and nurses.

The body's heat must be retained by clothing applied without delay, since the surrounding air is much below that of the uterus of the mother, to which it has till now been accustomed. This protection should not consist of the elaborate garments usually applied : pinning blankets, abdominal bandage, dresses with sleeves, etc., the child's body exposed while being applied. These are all abominations and should be abolished, and simple soft and warm and uniform clothing substituted without any pressure at any point whatever. The abdominal band should be loose and used for a week. Everything must be such as will allow absolute freedom to eat, sleep, and eliminate. These are the proper functions of the baby. The painful process of dressing and undressing is ridiculous to consider. The wonder is that the tender things are not killed outright. Samples of the garments used in the hospital referred to were displayed. A knit shirt, worsted, elastic but fitting fairly well. Thin soft flannel garments gathered about the neck, with blind, loose sleeves in one pattern, while in others there are no sleeves. These garments are puckered by a string below the feet. A padded diaper of absorbent cotton, applied sterilized, to be destroyed after use.

Developmental Needs in Children was the title of a paper by Dr. J. Madison Taylor, of Philadelphia. Education begins, as Dr. Holmes said, three hundred years before birth. The same is true of disease. What is inherited is not the disease itself but some weakness or tendency to it. Immunity hereditary, as yellow fever in the negro, and acquired, as in infectious diseases after an attack, was referred to as illustrative of the subject-matter. No doubt the effects of deleterious causes in the parent are felt in the child. Various diseases well known, alcoholism, lead poisoning, etc., are examples. Communication between some different races has been observed to have deleterious effects, as was shown in the case of healthy Swedes and Arabs producing offspring with strongly marked tubercular tendency.

Anything that will reduce cell-force reduces health standard and power of resistance to disease. Overwork was referred to as a potent factor at present in the rush we witness. It is time to calm down and take a rest, or future generations will sadly suffer.

The poor overworked school-girl crammed with useless learning at the expense of health, joy of life, and life itself, is a pitiful spectacle. It would be absurd if not so serious. Let's have it stopped !

Dr. O'Brien, of St. Paul, Minn., remarked that he too had his fad in treating children. He disagreed with one paper and believed that most children are born healthy, and if we leave them alone to breathe, eat, sleep, and eliminate, they will thrive. The first nursings should be in six hours apart, both breasts at each time, later every four hours. The children in the wild and woolly West are more likely to be killed by fond and unwise parents, in excess of anxiety and care. If they would only let them alone when they have their little natural disorders many more would live. He believed in prepared foods, and did not think it necessary to worry about sterilizing milk, since Nestle's Food is sterilized milk. Every child is a law unto itself and must be studied to find what these laws are and what food will best agree. He agreed in the main with Dr. Cotton regarding clothing, but believed in the abdominal band snugly applied.

Infantile Scurvy.—Dr. I. N. Love, of St. Louis, Mo., read a paper on "Some Points on Scorbutus in Children." Many observations in eleemosynary institutions have shown him that the disease is more frequent in private practice. The cases seen by him had occurred in feeble children. Histories were presented in detail. Five cases had been observed. It is most apt to be confounded with rheumatism. There is no doubt the disease is due to the absence in the system of certain organic acids, and these must be supplied by the feeding. The juice of fruits—a teaspoonful of orange-juice for a baby—is the most prolific source of supply. But proper feeding with ordinary foods, attending to digestion and assimilation of the foods taken, are also requisite and should be carefully and minutely taken into account. Digestion is not always proof of assimilation. We should have a food just as nearly as possible like mother's milk. There should be used fresh food, not killed by sterilization, if feasible.

Dr. Atkinson, of Baltimore, said, in regard to the paper, he did not deny the existence of the disease in children, but he had certainly never seen a case. The conditions for producing the disease are absent while the infant lives on the mother's milk. Regarding artificial foods there is prevailing misapprehension. Condensed milk is simply milk without its water, and it spoils in a few hours. Canned milk is another thing.

This is preserved milk in fact. It makes fat, but weak and flabby children. We have in marasmus and purpura hemorrhagica without scurvy in children. The teaspoonful of orange-juice, the speaker thought, might have had less to do with curing the cases than other wise measures employed.

Dr. Bishop, of Easton, Md., thought that one point, the prenatal care of infants, had been overlooked. One question so hinged upon another that it would not do to leave this part out. Children of weak constitutions, inherited or acquired, should not be too much encouraged to grow up. The practice in this direction in our institutions was an evil to society. Weaklings breed faster than healthy people. They should be allowed to die, and thus prevent the propagation of their kind.

In rebuttal Dr. Love said the prenatal feeding of the child is important. Even the condition of the mother at the time of conception. Even also the whole question of matrimony, as bearing on this subject. No one so well knows the very serious relations to the race as the physician. As to allowing the weaklings to die, where is the right-minded father or mother who would consent to this? The better instinct is always to save. Who knows where we have the germs of a Lincoln or a Shakespeare, or what possibilities may be present in the veriest weakling infant?

The speaker was sure that there was no question of diagnosis in his cases of scorbutus in children, nor in those of other observers. Those who see so many children, as in large cities, and have greater experience, he believes better authorities than those who see comparatively few in the country or small cities. Scurvy is abroad among children, and the general practitioner should be on the alert for it.

The Section was then adjourned.

SECTION IN MEDICINE.

Second Day, Wednesday, May 8th.

Some Points Concerning the Etiology of Tuberculosis.—A paper with this title was read by Dr. Frank E. Parsons, of Philadelphia. For the development of this disease in any one of its forms there must be what we call the pre-tubercular condition. The tubercle bacillus alone is as incapable of developing the malady as an ungerminated grain of wheat is to reproduce itself. It is the taking into the system of the bacillus, plus the pre-existing soil, which eventuates in the full-fledged malady. The results of autopsies show that this process begins in many individuals, and that the products either resolve or are discharged by suppuration, and the forerunner of the latter morbid process is always vascular stasis. Physiologically the circulation is either afferent or efferent. Anatomically it is arterial, venous, and capillary. The development of tubercle signifies that previous lymphoma or lymphangitis has altered circulatory conditions. Tubercle is therefore rather a sign of lymphatic stasis than a disease *per se*.

What is the cause of this lymph stasis? We know that acute irritation of tissues in burns leads to acute inflammation. Chronic irritation, as with alcohol on the stomach, leads to corresponding chronic proliferative changes. Unless the waste products of the body are removed by the lymphatic channels they accumulate and poison the system, but an excess of waste material may of itself cause venous stasis. We know that in phthisis the venous blood is of a brighter hue than usual, and that in this condition there is a deficiency of oxidizable phosphorus. If now we feed phosphorus to patients the venous blood reassumes its normal hue. Under this accumulation of waste products there first occurs stasis, then a paralysis of the nerve-centres, and finally an increased blood-supply, all previous to the entrance of the bacillus. The *rôle* of the latter as the sole etiological factor is not yet demonstrated by the result of animal injections. These are fallacious, as only those animals are affected who would get a lymph stasis from the injection of any substance, no matter what its nature might be. The general conclusions are —1, That primary tuberculosis is primarily due to lymph stasis, congenital or acquired, and, 2, that the tubercle bacillus is the phenomenon expressive of the disease, and is therefore symptomatic and not etiological, and that the so-called scrofula is merely a pre-tubercular stage.

Menthol in Tuberculosis.—Dr. DeLancy Rochester, of Buffalo, N. Y., next read a paper entitled "Report of Thirty-four Cases of Tuberculosis Treated by Carosso's Method." The writer has been much impressed by the reports of Carosso, of Genoa, as to the utility of menthol in phthisis. The latter has claimed that by absorption it promotes a general disinfection of the body, though he uses creosote also internally. His method is to fasten by tapes over the nostrils a piece of linen 10 ctm. square and folded once. On this he pours a few drops of essence of peppermint, having previously greased the nostrils so as to avoid intra-nasal irritation. The patient is directed to take eight or ten deep inspirations with closed mouth every fifteen minutes. He also swallows, every three hours, one teaspoonful (in half a glass of water) of the following mixture: Beechwood creosote, 8 parts; alcohol, 550 parts; glycerine, 250 parts; chloroform, 20 parts; and essence of peppermint, 8 parts. Over-feeding is also resorted to. Two or three litres of sterilized milk are taken daily, with meat cooked to taste, and four hundred to five hundred grammes of good wine. Sputa are carefully disinfected.

Carosso reports forty-four cases, with six deaths. Many were well advanced, and in all bacilli were found. The average time of treatment was sixty days. The thirty-eight recoveries seem to be permanent.

In the Erie County Hospital Dr. Rochester has given the plan of treatment a trial in thirty-four cases. Twenty-eight had cavities; four had infiltration of the right upper lobe, and two of the left upper lobe. In all the process was an active one, with afternoon fever. The previous treatment had been oil and creosote, on which they were doing well. No wine was given, but whiskey was used if stimulation seemed necessary. His results, however, were disappointing in the extreme. In two months all his cases were doing badly. The creosote cases, previously doing well, began in a week to share the same general fate. There was extreme gastric disturbance, even vomiting. The pad was complained of in one case as interfering with respiration, but all but one breathed much better and coughed less. The amount of sputa did not diminish.

The great criticism to be made on *a priori* grounds against this plan of treatment is the excessive amount of fluid introduced into the body. It means one pint every three hours, from 6 A.M. to 9 P.M., and one additional pint during the night. Too much milk and meat are, under the circumstances, incompatible. The lactic acid therein overcomes the hydrochloric acid of the stomach. In most phthisical cases the stomach is dilated, and the response of its musculosa to physiological stimuli imperfect. Such treatment would upset a healthy stomach.

The general conclusions of the paper were: 1. The internal treatment of Carosso is unphysiological, and upsets the stomach. 2. The inhalation of peppermint is a valuable method and deserves further trial.

In opening the discussion on the two foregoing papers Dr. Delano Ames, of Baltimore, gave his experience with the plan in the Johns Hopkins Out-patient Service. He had employed it in from eighty-five to ninety cases. Sixty were under treatment for a period of twelve months. His results tallied closely with those of Dr. Rochester. Carosso's claim that the bacilli all disappeared in from eighteen to sixty days had not been borne out in his own experience. Fully one-half his cases suffered from severe stomach dis-

turbance. In some instances weight rose at first, but afterward fell back. He thought that more solid and less liquid food would approach more nearly to an ideal diet, more starches, sugars, and fats, and these he had given. In all Carosso's cases the lungs alone were affected. In three-quarters of his own cases this was the condition. Bacilli were lessened and night-sweats diminished. He did, however, believe that peppermint lessened the dyspnœa. We have not yet been able to demonstrate that the peppermint is excreted by any of the emunctories under its own form.

Dr. Charles Denison, of Denver, Col., alluded to the serum therapy of tuberculosis. His own experiments on dogs had failed, for their serum when injected into men caused much urticaria and constitutional disturbance. Any remedy, as tuberculin, which he had used on dogs, was not necessarily increased in efficiency by being passed through an immune animal. He had given over six thousand tuberculin injections without a single abscess. He believed that our cure of phthisis must come about by our increasing the power of resistance in the given individual. This could be best brought about by climate and a high altitude. We must also render our patients immune. A German observer had noted that the red blood-cells in men and rabbits were increased sixteen per cent. in one month by a gradual change of residence from a low to a high altitude. Tuberculin is not suited for cases which have a high febrile range. But many cases on removal to high altitudes show a great improvement in capillary circulation. He had treated one hundred and twenty-seven cases with tuberculin, and of these he believed that he had cured twenty-seven. His own experience with the remedy had been satisfactory.

Dr. Karl von Ruck, of Asheville, N. C., took exception to what Dr. Parsons had called the "pre-tubercular" condition. It was in his view not only early but real genuine tuberculosis. Moreover, he did not believe that ulceration and suppuration are produced by stasis alone. The products of tuberculosis, as we find them, result not from stasis but from bacillary invasion. Experiments on animals are far too complete for us to doubt this. He did not attach much curative value to the peppermint inhalations, though he believed that they would help cough. When we consider the difficulty surgeons have in rendering any patent area of the body sterile, it is folly to suppose that inhalations of any kind can clear out the bacilli from pulmonary cavities. He endorsed the beneficial effect of high altitudes, though so many cases came to us suffering from mixed infections—from other things than pure phthisis—that it was impossible to do much for them. He thought that tolerance to increasing doses of any injected material was often mistaken for immunization, when in reality it was quite a different thing and merely comparable to the tolerance resulting from the use of alkaloidal drugs.

Dr. Parsons, in closing the discussion, stated that catarrh of the stomach was always met with in tuberculosis, and that it required careful treatment apart from all measures directed against the more formidable affection. Creosote he had not found good in gastric catarrh, and he did not use it internally.

Dr. Rochester added that he believed most thoroughly in increasing the resisting power of the individual; anything which reduces this is an element of the pre-tubercular condition. He did not believe in heredity, except as a poor constitution might be inherited. Some ten cases of fœtal infection were on record, but most children regarded as the subjects of congenital tuberculosis had become infected by the maternal sputa (kissing etc.), or by nursing from a tuberculous parent. It was a noteworthy fact that the so-called heredity was rarely through the paternal, but almost always through the maternal side. As to creosote, it could be palatably given in claret wine or mucilage of acacia.

Treatment of Tuberculosis with Horse-serum Injections.—Dr. Paul Paquin, of St. Louis, read a paper with this title. We have learned, the reader said, that tuberculosis exists in various regions of the body long before it gives any external symptoms. A patient may suffer pulmonary infection from his own glands rather than from outside sources. We are, therefore, unable to make a positive diagnosis until after the internal organs have become involved, for the commencing appearance of bacilli in the sputa is, unfortunately, not a sign of incipient tuberculosis, but rather of a distinctly progressive grade of the tubercular process.

In January of the present year the author reported to the St. Louis Medical Society the results of the treatment of twenty-two cases treated with horse-serum. The patients received one injection below and outside of the scapula daily for an average of two months. All improved and gained in weight, the gain being from one and one-half to twenty-two pounds in the course of the eight weeks of observation, and all are now living. They represented all grades of the disease, from infiltration up to cavity formation; all presented bacilli and all were distinctly emaciated. Several had had hemorrhages. Of a few additional cases since treated two had died in from three to five days after the treatment was begun, but they were hopeless when first seen. Absolutely no other treatment had been employed in all the cases. When the serum was stopped they grew worse, but improved again upon its resumption. The remedy seemed to diminish all the evidences of tubercular activity. Hemorrhages were arrested, appetite improved, cough lessened, and the venous irritability quieted. (Three patients who had been thus treated were exhibited, and an epitome of their clinical histories read.)

The remedy also seemed to promise good results in surgical tuberculosis. In one case of knee-joint disease removal of the diseased structures had been followed by serum injections with good results. As regards the production of the serum, horses were naturally immune to tubercular processes. First of all, an injection is made into the jugular vein of some culture media containing the toxins of the bacilli; when the animal ceases to react to this (as evidenced by the lack of fever and other constitutional manifestations), dead bacilli are injected, and finally living bacilli. When all reaction has subsided, blood is withdrawn from the vein, placed on ice, and the serum gradually allowed to separate. It is then filtered, and is ready for use.

It has been found that serum from a given animal varies in power after successive withdrawals from the vessels. Hence there is a variation in the effects of serum from the same animal upon patients. After a while the animal seems to develop certain toxins during the recuperation from the debilitating effects of the bleedings. Transportation seems to harm the serum, as various germs are apt to develop therein. We must not tap the horse too early after immunization, as under these conditions the serum does not seem to possess its maximum curative power. From ten to thirty minims are used for each injection, and camphor has been found to materially assist in keeping the serum in good condition. After the injection it has been observed that the face flushes and gradually becomes purplish for a period of four to five minutes, and a slight chill frequently follows. This does not always happen, and when it does occur it is probably to be explained by the fact that the needle has been thrust directly into a blood-vessel instead of into the cellular tissue. Arthritic pains have been observed, especially with patients who have previously been rheumatic. The urine is considerably diminished, and albuminuria has been observed in one case.

The discussion was opened by Dr. Karl von Ruck, who doubted whether any animal could be regarded as absolutely immune toward tuberculosis. To prove the position taken by Dr. Paquin we ought to kill the

animal and make careful pathological and bacteriological examination of its tissues. Our animal experimentation was not yet complete, and there was no proof that the serum had any power on either animals or men. Dr. von Ruck had tried Paquin's serum on guinea-pigs, and all had died within forty-eight hours. Granted, moreover, that the serum had effects on the bacilli, it was impossible to remove the results of tissue change which come from the condition of mixed infection which we so frequently find in ordinary phthisical cases. Insistence should be laid on the importance of early diagnosis from the clinical history and physical signs alone, for when we find bacilli it means that suppuration or tissue degeneration has already occurred. We should use tuberculin for its diagnostic value. The reader of the paper had spoken of the spores of tubercle bacilli. He (Dr. von Ruck) had never seen them, and, moreover, it was a matter of doubt whether this variety of germ had really true spores or not.

Dr. DeLancy Rochester, of Buffalo, called attention to the fact that many cases of phthisis recover without any treatment at all, and he could not believe that specific treatment had any place in cases of mixed infections.

Dr. Henry D. Holton, of Vermont, stated that the serum of the ass would probably be superior to that of the horse, as there was little fatality from phthisis in those countries were the milk of the ass was used. The juice from the muscle of animals in whose muscles no tubercles are found, but who have tubercle elsewhere, has been found to produce the disease ; also milk from cows who, though tuberculous, had healthy udders and no bacilli in their milk.

Dr. Paquin, in closing the discussion, admitted that the serum might occasionally contain some cocci, but that they were not necessarily harmful. The same was the case with Behring's serum, and yet everybody used it. As to spores, he believed that he had seen them, as they gave the stain reactions of tubercle bacilli. The blood of asses he had no experience with ; mule-serum seemed to be the same as horse-serum, but he did not deem it prudent to use it, as the former animals are very subject to a disease resembling rheumatism in man.

Pulmonary Hypertrophic Osteo-arthropathy was the title of the next paper, by Dr. N. S. Davis, Jr., of Chicago. One similar case in this country had been reported by Packard, in the *American Journal of the Medical Sciences*, in June, 1892. The European literature of the last five years contained the histories of some forty cases. The first work was done in 1890, by Marie, and the disease had since been known by his name. It had to be distinguished from acromegalia. The essential lesion seemed to be a chronic multiple osteitis of the terminal phalanges and of the ends of the long bones. The cause of the osteitis was probably some poison absorbed from the lungs or pleuræ. Cases had also been observed in connection with congenital heart disease, syphilis, and spinal caries, but in general the association was with suppurative diseases in the respiratory tract.

As to the nature of the disease several theories were held. Some regarded it as an attenuated tuberculosis, others as a trophic nerve affection, still others as due to caries of the spine, while, as above suggested, three cases had been observed in syphilitic disease. No heart or lung disease was evident in these latter, but in the spleen and liver of one case bacilli were found. Pulmonary hypertrophic osteo-arthropathy therefore was rather a symptom group and not a disease *per se*. It was probably a toxæmia from the respiratory tract.

The case described by Dr. Davis was that of a boy, aged about four, with cough and periodical expectoration of pus dating back to a pneumonia one year before. There was an enlargement of the fingers, toes, and wrists, and curving of the nails. The skin and glands seemed normal and the body was well nourished. There was no kyphosis or scoliosis. On the left side of the chest there was a bulging and immobility in respiration, with dulness, and displacement of the heart to the right, in fact, all the symptoms of a pleural exudate compressing the lung. It was believed to be purulent, and the purulent sputa were probable periodical drainings off of the exudate through a bronchus. At such times there was fever and the usual pus reaction. The symmetry of the bone and joint lesions was a feature of the disease. In previous cases the urine had been reported as normal.

As to a diagnosis from acromegalia, the latter, it should be remembered, was chronic. The enlargement of the fingers was uniform. The kyphosis, when present, was cervico-dorsal, but in the arthropathy, dorso-lumbar. The seat of the lesion in acromegalia was the pituitary body, and there were generally visual disturbances.

Dr. S. Solis-Cohen stated, in discussing the paper, that he had seen two cases which might fairly come under this category. In acromegaly the hand was broadened as a whole, while here it seemed lengthened. Kyphosis was frequently present in tuberculosis, and with his present knowledge he was inclined to regard the arthropathy merely as an exaggeration of what we commonly see in tubercular disease. The wrist and ankle enlargements are suggestive, as in acromegaly these two points are not involved. The trophic disturbances apparently led to the development of certain structures at the expense of others, and they were probably due to some pus toxin.

Measures Calculated to Modify Acute Inflammation of the Respiratory Tract was the title of the next paper, read by Dr. H. B. Sears, of Beaver Dam, Wis. The majority of deaths in acute respiratory diseases occur from excess of the mucous secretions or from heart failure. These clinical phenomena are met with in two classes of patients ; first, spare people poorly nourished, whose nutrition was principally at fault ; and second, stout people, with more or less cyanosis, rapid pulse and breathing, and complaining greatly of thirst. In both there was feeble heart action, with a resultant overloading of the veins and capillaries. A great mistake was frequently made in giving too much fluid to these patients. Heart stimulants alone were of limited applicability, as we could not overforce a debilitated organ. We should first purge freely so as to relieve vascular overloading, and then the exhibition of heart stimulants would be followed by gratifying results. Next, the excess of secretion should be combated. This procedure was far preferable to emesis in children, or the lancet in adults. Belladonna and turpentine were the remedies mainly relied upon by the reader to lessen secretion. For a heart stimulant digitalis was useless in high temperature, as it was not absorbed. With the plan above outlined, anodynes and antipyretics are more rapidly absorbed.

Hydrotherapy in Fevers ; its Rationale and Technique, was the title of the next paper, read by Dr. A. H. Burr, of Chicago. He gave a general description of the febrile state, setting forth that the high temperature is the result of a toxic derangement of neural resistance to, and neural control of, the heat-making apparatus of the body. Too much effort had been made merely to reduce the temperature in febrile conditions. The numerous coal-tar derivatives marked the height of this craze.

In the application of the cold bath we should always bear in mind the physiological action of water. It is a neural stimulant ; it affects the sympathetic nervous system and thereby exercises a direct control over the glandular system ; by its reflex action it has a marked influence upon circulation, respiration, metabolism, elimination, and pyrexia. Winternitz has shown that after a cold bath there is increased leucocytosis, increased hæmoglobin, and increased specific gravity of the blood. Thayer had shown similar results in examining a drop

of blood taken from the ear of a patient who had received cold baths. The increased leucocytosis was too marked to be explained by cell proliferation. It was probably due to the fact that the increased circulatory activity swept out into the general current the cells which had become lodged in the various corners of the vascular system.

Dr. Burr then exhibited a wooden frame to be placed over the bed for bathing febrile cases. Under the patient was slipped a rubber-sheet, which had tapes on its sides. These were brought up over the frame and fastened thereto, so that a tub was improvised capable of holding twenty gallons of water, which after use could easily be siphoned out. The whole apparatus was portable and easily manipulated.

The discussion was opened by Dr. N. S. Davis, Jr., of Chicago. He did not believe that bathing shortened the course of fevers, but it did lessen danger and made the patient more comfortable. A rise of temperature meant toxic absorption. The so-called typhoid state was found in other diseases than typhoid fever. It meant perverted metabolism, and we should remember that we are treating this state rather than one of infection.

Dr. Boylan, of Pittsburg, Pa., insisted upon the importance of keeping the skin thoroughly clean in all febrile states, and this is one of the good effects of the bath. He declared that death would result in three hours if the respiratory function (so called) of the skin was completely checked.

Dr. Webster, of Chicago, doubted the truth of this last statement. Death had ensued in animals whose skins had been coated with varnish or similar substance, but it had been due to loss of heat. If the varnished animals were enveloped in cotton, or their external heat kept up, they did not die.

Dr. C. G. Stockton, of Buffalo, heartily endorsed the position taken by the reader of the paper, and made a plea for the use of the bath in small communities.

Dr. S. Solis-Cohen thought that any sheet-arrangement is disadvantageous in that it brings merely small pools of water in contact with the patient. The good effects of immersion were thereby lost. Dr. Burr's device was doubtless next in utility to a tub.

Dr. F. B. Turck, of Chicago, believed in baths of water at 95° raised to 115° F., or until there was marked dilatation of the superficial vessels. Then the patient should be rubbed down with ice, and cold water applied in douches with the syringe. In conditions of passive congestion such a procedure would restore the equilibrium of the circulation.

Dr. DeLancy Rochester, of Buffalo, insisted that the most important thing in bathing was the continuance of gentle friction over the body during the entire immersion. The water was more important as a nerve tonic than as an antipyretic.

Dr. James Tyson, of Philadelphia, said that most of the cases which had died during his practice under bathing had succumbed to perforation or hemorrhage. He was a firm believer in the bath.

Dr. J. M. Anders, of Philadelphia, while an advocate of bathing, believed that there were contra-indications thereto. As soon as intestinal hemorrhage occurred he stopped the bathing for a while.

Dr. Burr, in closing the discussion, said that he believed that the Brandt method, while not curative in every case, did nevertheless alter the entire aspect of typhoid fever for the better. He believed that the profession in America was culpably negligent in not using it more generally.

Atypical Gout.—The closing paper of the session, by Dr. James Tyson, of Philadelphia, was entitled the "Symptomatology of Irregular or Atypical Gout." His object was to insist upon accuracy in nomenclature. He alluded to the recent views of Garrod and Roberts to the effect that the causative uric acid existed in the blood in the form of a quadriurate of sodium. There was no difficulty in diagnosticating typical frank gout, but there was often trouble with the incomplete form. Among the atypical gouty manifestations noted were dyspepsia, deposits of lithiates in the urine, eczemas, muscular pains, deep-seated pain in the tongue, crackling feeling about the cervical spine, pains in the back of the neck and loins, adductors of the thigh and gastrocnemia; also articular pains and nodosities, headache, pains in the palms of the hands, folliculitis of the nose, scleritis, keratitis, conjunctivitis, asthma, bronchitis, tonsillitis, pharnyngitis, dryness of the tongue; also inflammations of the bladder and hemorrhages thereinto. There was also a cerebral gout, characterized by a capriciousness, melancholia, insomnia, and changes of temper. He laid especial stress upon the importance of recognizing a possible gouty cause in cases of vesical hemorrhage.

He would in the diagnosis of a suspected case lay special stress upon the following points: 1. A condition of uricacidæmia, but it was rarely possible to diagnose uric acid in the urine with the means in the hands of the general practitioner. 2. The supervention of regular gout on the subsidence of other ailments or alternations between the two clinical conditions. 3. A history of previous typical gouty attacks. 4. Heredity. 5. A history of exposure to lead poisoning. 6. The general habits and mode of life of the patient. 7. Scanty and highly colored urine. This might also occur in lithæmia. 8. Glycosuria. 9. Chronic interstitial nephritis, which was the fatal goal toward which all these other symptoms invariably led. 10. The result of therapeutic measures.

Dr. Stockton did not believe that lithæmia led to gout in all cases.

SECTION ON OBSTETRICS AND DISEASES OF WOMEN.

Third Day, Thursday, May 9th.

Present Status of Treatment of Fibroids of the Uterus by Electricity.—Dr. A. Laphthorn Smith, of Montreal, stated that while he thoroughly believed in the operative treatment of fibroids of the uterus, he still saw good in the electrical treatment in certain cases. Electricity is not suitable for every kind of case nor for every kind of doctor, but it is as true to-day as it ever was that for the cure of pain and bleeding, the positive pole of the galvanic current, properly applied, is in the majority of cases effective. The percentage of successes is greatest in those cases in which the fibroid growth is interstitial; it is not quite so great in the sub-mucous variety, although in some cases it has been followed by the expulsion of the tumor from the uterine cavity. The plea for the early treatment of fibroids by electricity is quite as just as that for operative treatment, and even more so. It is entirely devoid of danger, which we cannot say of the operative treatment. One serious objection to the electrical treatment is the length of time it takes to apply it properly. The present status of the electrical treatment is not as good as it should be because it has been tried by men of insufficient experience and therefore been found wanting. The fact, first mentioned by Apostoli, that electricity produces a febrile reaction when the tubes are badly diseased, is of diagnostic value. It is not true, as has been claimed by some, that applications of electricity cause adhesions.

In conclusion, Dr. Smith said that although at present the tide of surgery is in its full flow, the time will yet come when electricity will find an honorable place in the treatment of women who wish to keep their ovaries.

The Treatment of Hemorrhagic Conditions of the Uterus by Zinc-amalgam Electrolysis.—Dr. G. Betton Massey, of Philadelphia, read a short paper on this subject, in which he advocated, in the galvanic treatment of hemorrhagic endometritis, the use of an intra-

uterine electrode composed of zinc freely amalgamated with mercury. By this means the zinc surface is always keep smooth, lubricated, and non-adhesive, and a new value is attained in the use of a nascent oxy-chloride of mercury in addition to the oxy-chloride of zinc, with far more efficient alterative and antiseptic results.

Diseases of a Reflex Nature Arising from Pathological Conditions of the Uterus and Appendages.—Dr. W. H. Humiston, of Cleveland, O., read a paper on this subject. Among the more prominent reflex phenomena mentioned by the author which may be the result of pathologic conditions of the uterus and its appendages were the following: Anæmia, headaches, fulness of the head, neuralgia, neurasthenia, pain in the spine, insomnia, epilepsy, nausea and vomiting, dyspepsia, obstinate constipation, gastralgia, irritable heart, pain in rectum, frequent and painful micturition, general irritability, inability to walk, eye symptoms, hysteria, and hypochondriasis. The conditions of the pelvic organs in women should always be carefully ascertained, or else one is likely to err in his diagnosis of the symptoms complained of. In conclusion, Dr. Humiston reported a number of cases of this character coming under his observation.

Remote Results of Removal of the Uterine Appendages.—Dr. E. E. Montgomery, of Philadelphia, read this paper. The author stated that the most marked influence of this operation is upon the nervous system, and is the result of the fact that the climacteric, which is always a critical period in a woman's life, has been abruptly induced, without nature having had an opportunity to prepare her for the changed relation. Among the nervous phenomena that have been noted in these patients are the following: Neuralgia, neurasthenia, pain in various regions of the body, insomnia, restlessness, and irritability of temper. Even if the individual may have had no desire for offspring, the assurance that motherhood is denied her frequently leads to intense longing for a child. The declining sexual appetite not infrequently leads to a profound melancholy. Changes in pigmentation have been observed. The nervous phenomena may be actuated or aggravated by the sequelæ of the surgical procedure, such as fistulæ, ventral herniæ, painful cicatrices, intestinal adhesions, cellular exudations, etc. The conclusions drawn by the writer were as follows: 1. No mutilation or sacrificial operation should be done where there is a reasonable probability of relieving the inflammatory condition through vaginal incision and drainage. 2. Efforts should be made to preserve portions of an ovary and a tube through resection, where partially diseased. 3. Where the ovaries and tubes are diseased to such a degree as to require their complete removal, the patient is less likely to suffer from profound nervous phenomena if the operation be associated with hysterectomy. 4. Castration should be done for neuroses only after it has been demonstrated by the experience of capable neurologists that the operation is the *dernier ressort*.

Dr. Henry Newman, of Chicago, said he has never seen a case in which removal of the uterine appendages produced insanity or an outward physical change in the patient; nor has he seen it result in any sexual deterioration. He expressed the opinion that before the operation is performed, its possible ill results should be carefully placed before the patient. Furthermore, it should only be performed for actual structural changes in the appendages.

Dr. Ward, of Kansas, said that where healthy ovaries are removed in young women, very marked nervous symptoms are produced. He has never seen insanity result from it, however, nor a loss of the sexual appetite. The operation is usually followed by a very troublesome leucorrhœa. In all cases it is well to postpone the operation as long as possible. We shall probably see the time when, where ovariotomy is demanded, the uterus will be removed also.

Dr. Rufus B. Hall, of Cincinnati, said he has frequently seen patients suffer from mental depression for temporary periods following the removal of diseased appendages. In one instance, insanity followed. In that case the patient was of a hysterical character, and there was a family history of insanity, two of her sisters having died in an insane asylum.

Dr. Massey said he has seen a number of cases in which physical and nervous disorder followed the removal of the ovaries. In one instance it produced melancholia. In many cases, after the removal of the ovaries in young girls, a change is produced in their moral nature; the sexual feeling is not extinguished, and they can gratify it without running any risk of becoming pregnant. He has never seen an extra growth of hair on the face or elsewhere result from the operation.

Dr. Howard A. Kelly said that when a woman asks him what bodily changes will follow the operation, he tells her that she will get stouter, that she will look better and feel better. The possible loss of sexual power does not militate against the performance of the operation, because these patients are usually in such a condition that they have not enjoyed sexual intercourse for years. On the contrary, the operation often restores the family relations.

Vaginal Fixation in Retro-Deviations of the Uterus.—Dr. X. O. Werder, of Pittsburg, read a paper on this subject. He stated that this is the newest addition to our operative treatment in the backward displacements of the uterus. It is the result of a gradual evolution of Schücking's method, and its modifications by Zweifel and Sänger, and was originated in its present form by Dührssen and Mackenrodt, both of whom claim priority. Dr. Werder then described the technique of this operation, and stated that the failures that have been reported are due to the fact that the fixation sutures were inserted too low down in the body of the uterus. In order to guard against a return of the malposition, the fundus must be sutured to the vagina. Dührssen, in all his more recent cases, opens the peritoneum as soon as the bladder has been separated from the uterus, and this permits the operator to see the exact point where he wishes to insert his sutures, which is at the fundus between the cornua. Dr. Werder stated that up to the present time he has performed vaginal fixation of the uterus by the intra-peritoneal method seven times without a single failure, although they are all too recent to justify an opinion as to the permanency of the result, all of them having been operated on within the past seven months. In all cases, the operation of vaginal fixation should be preceded by a thorough curettage.

The intra-peritoneal method of vaginal fixation, termed "vaginal cœliotomy," by Dührssen, has, besides permitting of a more satisfactory fixation of the uterus, the great advantage that it allows the fundus to be drawn down to the vulva and outside of it, and with it the adnexa, which can then be carefully examined, both by touch and visual inspection.

Extra-uterine Gestation; Its Early Diagnosis and Treatment.—Dr. S. L. Jepson, of Wheeling, W. Va., read a paper on this subject. The following were his conclusions: 1. Extra-uterine gestation is probably always primarily tubal; the ovarian is a possible rare exception. 2. Diagnosis before rupture may often be made with reasonable certainty. In some cases it is impossible. 3. Diagnosis after rupture can in most cases be made so certainly as to justify opening the abdomen. 4. Electricity—preferably galvanism—should be used when a diagnosis is made before rupture, unless the patient can and will secure the services of an expert operator. 5. Cœliotomy by an experienced abdominal surgeon is always proper in early unruptured cases. 6. After intra-peritoneal rupture with free hemorrhage, the abdomen should be promptly opened and the tube grasped near the uterus. The operation may be com-

pleted at once or delayed to restore the patient, as her condition requires. 7. After rupture into the broad ligament, abdominal section is not urgent, and often is unnecessary. 8. While condemning operations by the inexperienced in cases of no urgency, yet an emergency may arise after intra-peritoneal rupture, when cœliotomy by the inexperienced may become a duty, but this should never be resorted to without counsel.

Dr. A. H. Goelet, of New York, said he did not think an operation was demanded in every case of extra-uterine pregnancy. In the first place, the necessity of the operation is the danger of rupture, and that danger is removed if the death of the fœtus is accomplished. That can unquestionably be done by electricity. If rupture has taken place between the folds of the broad ligament, it is admitted by some of our best authorities that it is comparatively harmless and may be left alone. He has had several cases of this character, and they resulted very satisfactorily by leaving them undisturbed until the ruptured vessels sealed up, and then, where necessary, emptying the sac through the vagina. In this way we avoid opening the abdominal cavity. Statistics show that even when the hemorrhage occurs within the peritoneum it is seldom sufficiently severe to demand cœliotomy for its arrest. Of course no one would hesitate to open the abdomen in cases where the bleeding is very severe, but if it has ceased it is far safer to let it alone.

Dr. Rufus B. Hall said it is often difficult to decide whether rupture has occurred between the folds of the broad ligament or directly into the peritoneal cavity. In fifteen cases coming under his observation, a diagnosis of rupture into the broad ligament was made in every instance, and they were treated as such for varying periods; later on, in operating for the removal of the blood-clot, it was proven in every case that the rupture had occurred into the peritoneal cavity. We should assume primarily in these cases that rupture has occurred into the peritoneal cavity and be governed by the condition of the patient as to when we shall operate.

Dr. James E. Reeves, of Tennessee, said that these cases are not infrequently met with in small country towns, where the assistance of an experienced surgeon cannot be readily obtained, and he expressed the opinion that in such an emergency any physician who has an ordinary knowledge of the anatomy of the parts and who has the boldness to use the knife should not hesitate to operate. While he has personally had but little experience with electricity, he did not think it should be relied on in extra-uterine pregnancy.

Dr. A. Lapthorn Smith said he was in favor of operating for extra-uterine pregnancy as soon as the diagnosis is made. He regarded it as one of the easiest of the abdominal operations.

Dr. Tod Gilliam, of Columbus, O., said that while there is nothing easier than an operation for a simple case of extra-uterine pregnancy taken early, there is nothing more difficult to handle than a complicated case that has been going on for some time. Such a case requires all the knowledge and dexterity of an expert.

Drs. J. M. Coble, of Dallas, Tex., and John M. Duff, of Pittsburg, continued the discussion, which was then closed by Dr. Jepson.

Suspensio Uteri; the Proper Method of Performing it, and its Results.—Dr. Howard A. Kelly, of Baltimore, read a paper on this subject. He stated that he prefers the name "suspensio uteri" to that of "ventral fixation," because the uterus is not fixed at all; on the contrary, it is freely movable after the operation. The indications for the operation are extreme local discomfort associated with retroflexion which cannot be relieved by local treatment. Other indications are where there is general prostration, headache, and the neurasthenic condition associated with the retroflexion which produces more or less local discomfort. Up to the present time he has performed the operation in one hundred and seventy cases. Of these, none died. There were stitch abscesses in three cases. In one case (in which the appendages has also been removed) there was secondary hemorrhage in the abdomen; in one there was transient mania. Bladder symptoms were noticed in four cases. In almost every case operated upon there was considerable relief, and the vast majority of them have gone on to a complete and satisfactory recovery of health. A number of the patients have since become pregnant and been successfully delivered. In one case the uterus remained in place for two years and then again became retroflexed. Dr. Kelly then described the technique of the operation, which he stated was very simple. It consists essentially of stitching the posterior wall of the uterus to the abdominal wall by means of silk.

Notes on two Cases of Pelvic Surgery Intended to Throw some light on Ventral Fixation.—Dr. H. R. Holmes, of Portland, Ore., read a paper with this title, and reported two cases upon which he had operated by Dr. Kelly's method. He also regards the operation as very valuable in certain extreme anterior displacements of the uterus.

Dr. A. Lapthorn Smith said he was very much indebted to Dr. Kelly for this operation, which he has now performed twenty-six times without any mortality rate and with very gratifying results. He referred to the importance of scarifying the peritoneum and anterior surface of the uterus for the purpose of favoring adhesion. He employs a permanent sterilized silk ligature in stitching the uterus to the abdominal wall. The organ is quite movable after the operation. He considers it preferable to Alexander's operation.

Dr. Reuben Peterson, of Grand Rapids, said that in seventeen cases he has suspended the uterus by means of the ovarian ligament, which method was recommended by Dr. Kelly before he devised the present operation. In all excepting two cases the result was very satisfactory.

Dr. Hall said he has done the operation a number of times and was very much pleased with it.

Dr. J. H. Carson, of Detroit, said that in ordinary cases of retroflexion without any adhesions he did not think ventral fixation was required. They can be treated by mechanical means. Some of these women do not complain of any symptoms whatever. The operation is called for, however, when there is displacement due to disease of the appendages. He was surprised to hear that Dr. Kelly still employed silk for ligatures in these cases, and thought it would be better to employ some absorbable material for that purpose.

Dr. McConnagle, of San Francisco, said he has performed the operation a number of times with very good results. He does not think it is necessary to scarify the tissues.

Dr. Ward said he did not agree with Dr. Carson as regards the benefit of mechanical treatment. Even where there is no apparent disease of the appendages you may keep on treating these patients mechanically for an indefinite period without doing them much good.

Dr. G. R. Feil, of Cleveland, referred to a case in which fatal secondary hemorrhage followed the performance of the operation.

Dr. Kelly, in closing the discussion, said he now employs the posterior surface of the uterus instead of the ovarian ligament in suspending the uterus, because it is a little easier and quicker. The results by both methods are about the same. With an absorbable suture the uterus will only remain forward as long as the suture holds.

Symphyseotomy.—Dr. Hugh Hamilton, of Harrisburg, Pa., read a paper on this subject, and illustrated the same by means of a number of drawings.

The Therapeutic Action of Chloroform in Parturition.—Dr. Bedford Brown, of Alexandria, Va., read the paper. The author stated that in spite of the fact that

chloroform is so universally employed in obstetrical work, and often so carelessly administered, very few accidents have resulted from its use. This he attributed to the fact that coincident with the growth of the fœtus and placenta there are developmental changes in the maternal circulatory and vasomotor structures to supply the increased demand made upon them; the power of the left ventricle of the heart is increased, as well as the arterial tension, and this prevents the cerebral anæmia which always precedes collapse in fatal cases of chloroform narcosis.

Dr. Brown said he regarded the use of chloroform justifiable in every case of confinement where the labor is slow and painful. He has never been able to find a good substitute for it. In many instances it facilitates the process of parturition. The amount given can be carefully graduated, so that it will relieve the pain without impairing the strength of the uterine contractions. Its well-known power to relax muscular rigidity also facilitates labor.

The Vaginal Route for Operations on the Pelvic Viscera.—Dr. Tod Gilliam, of Columbus, O., read a paper on this subject, in which he referred to the advantages and disadvantages of operating by the vaginal route, as compared with the abdominal. Among the advantages of the former are that it leaves no scar, there is no danger of a subsequent hernia, the abdominal viscera are not handled, and the fact that many women will submit to it who will not allow the abdominal incision. He expressed the belief that, in spite of these advantages, the vaginal route will never supplant the abdominal one, nor in a large measure infringe upon it. With a narrow, deep, or unyielding vagina even the easier operations are rendered impossible.

Treatment of Contractions or Stenosis of the Uterine Canal.—Dr. W. A. B. Sellman, of Baltimore, read a paper on this subject and exhibited an instrument which he has devised for the purpose of removing such obstructions. The instrument is made in different sizes, and works very much like a pencil-sharpener, paring away the tissues in slices.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Joseph Taber Johnson, of Washington, D. C.; *Secretary*, Dr. Reuben Peterson, of Grand Rapids, Mich.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, May 2, 1895.

Joseph D. Bryant, M.D., President, in the Chair.

Memorial Services for the Late Alfred Lee Loomis, M.D., LL.D.—Addresses were delivered by Lewis A. Stimson, M.D., Rev. Henry M. MacCracken, D.D., LL.D., Chancellor of the University of the City of New York, and Hon. Abram S. Hewitt, LL.D, Ex-Mayor of New York City. The large hall was filled to overflowing by the many friends and admirers of Dr. Loomis from among the profession and laity. A more forcible example of the influence of Dr. Loomis's mind over the minds of his fellow-men could hardly be given than that of its power, even some months after his death, to determine the character of the addresses delivered on the occasion of these memorial services. While eulogistic, eloquent, earnest, and sincere, it was evident that the speakers had been inspired by that strong attachment for the man which all felt who had ever been brought in friendly relations with him, and that the deceased's own love for statements limited strictly to truth and facts had restrained them from undue adulation.

Dr. Stimson spoke more particularly of Dr. Loomis's work in connection with the medical department of the university, with other medical institutions, and of his professional career; Chancellor MacCracken of his interest in the collegiate department of the university; Mr. Hewitt of his services to the Health Department of the city and of his public spirit, while all dwelt upon his earnestness, vigor, power, practicality, upon his moral worth and attachment.

Dr. Loomis was born in Vermont, began practice in New York at the age of twenty-three with no resources but his moral and intellectual powers, and even with these hampered by a body which already showed the early symptoms of a disease, pulmonary consumption, which had robbed him of his parents and immediate relatives. Poverty was not his chief incentive to labor, for long after having acquired a competency he was still accomplishing an amount of work of which few men were capable. It was ambition. He had once said to Dr. Stimson on a public occasion that he would never rest until he stood in that man's place; and if the vow failed of literal fulfilment it was only because, when the prize was fairly within reach, it proved, like so many others which have blazed before the eyes, much less worth having than it had seemed. Other interests had arisen, other obligations had been assumed, other laurels had been won which were greater.

Dr. Loomis was from the first looked upon as a man of great promise, and he was successful from the start. He was always at work, always energetic, and his energy was eminently practical. At one time he had some thoughts of taking up surgery, but was soon found giving special attention to physical diagnosis and diseases of the heart and lungs. His success was such that he became Teacher of Physical Diagnosis in the College of Physicians and Surgeons. But his health now broke down, and his fear that with his hereditary history he would not survive thirty seemed likely to be realized. He left the city and went to the Adirondacks. After staying there six months his health was restored and he re-entered upon his professional career. Profiting by this warning, every year thereafter he spent some months in the mountains, and through his example this region became a favorite resort for invalids with pulmonary troubles. It had led to the establishing of a sanitarium at Saranac Lake, under the direction of Dr. Trudeau, and more recently of a home for consumptives which, through Dr. Loomis's influence, was aided by the gift of $60,000 from Mr. Morgan.

Dr. Loomis's greatest work was in building up the University Medical College, having succeeded to the chair of Dr. Metcalf, in Practice of Medicine, in 1866. The college was then at low ebb, had lost its building by fire, and its students, drawn largely from the South, by the recent war. Within five years Dr. Loomis had become its virtual head, within ten years it had reached the highest pitch of prosperity which it had ever known, and more recently, through his influence, it had been cleared of debt and a magnificent laboratory had been added. It was his energy, his push, his reputation, his purse which had sustained the school in its darkest days.

Dr. Loomis accomplished similar results in various other fields. He had been largely instrumental in giving Bellevue Hospital its excellent service. Probably no member of the profession was as often asked to aid by his recommendation or his active support candidates for hospital and dispensary positions, and with good reason, for he made the applicant's cause his own, and fully shared his disappointment in defeat if not his elation in success. He took an active part in medical society work, in the management and in the scientific discussions. He had been chosen President of various medical bodies, including the New York Academy of Medicine and Congress of American Physicians and Surgeons. When spoken to about office his answer was, "I should be gratified to be chosen, but I will enter upon no contest for it. I will not even be a candidate." When he became President of the Academy the work of completing the new building, as in every other work which he undertook, was always on his mind. The subscription-book lay open upon his

office table, and no patient worthy the effort lost an opportunity to subscribe.

Mr. Hewitt thought his wonderful success in soliciting subscriptions to worthy purposes was due less to the donor's interest in or knowledge of the cause advocated than to his implicit faith in Dr. Loomis. He knew that the gift would be used exactly as represented, and that the object must be a good one to enlist Dr. Loomis's effort. Mr. Hewitt spoke of his love of nature—of the woods, the mountains, the sunshine, and pure water. Both he and Chancellor MacCracken referred to his essentially religious nature. He had no theological doubts. He loved and labored for his fellow-men.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

ROYAL COMMISSION ON TUBERCULOSIS — THE OPIUM AND HEMP DRUGS REPORTS — MEDICAL SOCIETY — PARACENTESIS OF CHEST THIRTY-SEVEN TIMES — SCLEROMA NEONATORUM.

LONDON, April 27, 1895.

REPORTS of commissions are to the fore this week. Precedence to the Royal Commission on Tuberculosis. The results of this important investigation will be received with serious attention and perhaps excite such grave apprehension that legislation may follow. The commission is satisfied that an appreciable part of tuberculosis in man is contracted through his food—that is, the meat of tuberculous cattle. There is danger in such food, from any diseased organs unremoved in dressing, and from minute tuberculous deposits in the tissues of the muscles. Worse than this, particles of tuberculous matter are carried to healthy parts and to joints of healthy carcasses on the knives and cloths used by the butchers in dressing. This is a most alarming conclusion, for in spite of suggestions in the report to minimize the danger, is it likely that we can ever inspire ordinary butchers with the dread of germs and the details of aseptic cleanliness which even some surgeons find it difficult to perfectly follow?

"Sterilize your food!" some will exclaim. But even this is not so easy, for the commission reports that although cooking will destroy infectiveness on the surface it will not affect particles in the interior. In the case of rotted joints any particles smeared on the surface would necessarily be carried to a point where cooking would not destroy them. This is certainly a most disquieting conclusion. Still perhaps, something can be done. At any rate there can be no reason why we should not adopt all the precautions which other countries have found practicable. Legislation will no doubt be called for, though the commission does not expect much from this. Still, it is a question for legislation as well as one on which the public needs instruction.

The Royal Commission on Opium and the Indian Commission on Hemp Drugs have also issued their reports. Both are a surprise to many, the conclusions being in direct opposition to the statements so commonly made as to the evils of these drugs and the extent of their use or abuse.

On Monday last, April 22d, at the Medical Society of London, Dr. S. West related the case of a woman, aged thirty-one, sent to him with a history of having fluid in the chest and abdomen for eighteen months. On tapping the abdomen no fluid returned. He next tapped the pleura and removed ninety ounces of clear fluid. The fluid reaccumulating, paracentesis was repeated at frequent intervals for nearly twelve months, the operation being performed in all thirty-seven times, the fluid remaining serous throughout. With grave misgivings he consented to the chest being opened. An empyema developed, and for a time her condition was critical, but ultimately recovery set in and from that time was uninterrupted. The side rapidly contracted and the lung expanded, and at present the side is completely healed.

Dr. Hall held that it was always undesirable to open the chest in cases of simple serous effusion, a rule from which even the successful issue in this case would not induce him to depart. He himself had tapped the chest in one case thirteen times, and would tap "seventy times seven," if need be, so long as the fluid remained clear. If the fluid became purulent, he said it would probably be the fault of the operator. He recalled some statistics published by Dr. Barre, of Leeds, who showed that half the cases of simple effusion died of pulmonary tuberculosis, whereas of the patients suffering from empyema phthisis constituted but a fraction of the deaths. He inferred therefrom that the conversion of a simple into a purulent effusion could not *per se* facilitate the supervention of tuberculosis.

Dr. Coupland suggested that an obstinately recurring effusion was presumptive of its being dropsical rather than inflammatory, of which he gave an instance.

Dr. Routh said that the opening of the abdomen in cases of abdominal tuberculosis as a result of a mistaken diagnosis has been often followed by cure, and he failed to see any reason why the same thing should not hold good of pleural tuberculosis.

Dr. West said, in reply, the advice given in text-books to abandon paracentesis after two or three trials followed by recurrence required to be modified, for no risk attached to repeated paracentesis if the operator was careful to keep his instruments aseptic. He pointed out that in abdominal tuberculosis simple tapping was often enough to determine a cure, so that there was no necessity to open the abdomen.

Dr. A. Garrod related the case of a child first seen when aged five weeks, who at birth presented the characteristic lesions of scleroma neonatorum, the indurations commencing on the buttocks and spreading to other parts of the body. The child was otherwise in good health, and ultimately recovery took place. He commented on the fall of temperature observed in these cases, and discussed the differences between this condition and that of œdema neonatorum. The treatment adopted comprised inunctions of cod-liver oil and blue ointment, but he pointed out that in all probability the mercurial treatment did not do more than expedite recovery, and was not to be taken as evidence of the syphilitic origin of the disease.

Dr. Keser mentioned that he himself had gone through a severe attack as a child, having recovered under the influence of warmth, without mercury. He called attention to a number of incomplete and abortive cases which had come under his observation during the last few years.

Dr. Colcott Fox said that while in typical cases it might be possible to distinguish between scleroma and œdema neonatorum, a differential diagnosis might be difficult and even impossible in less well-marked cases.

Dr. Colman urged the fallacy of attributing the disease to syphilis from the effects of a mercurial treatment. A syphilitic history is usual in œdema neonatorum as distinguished from scleroma neonatorum, and in two cases he had demonstrated post mortem marked evidence of visceral syphilis within a fortnight of birth.

Suicides in France are increasing actually as well as relatively. The annual average for the years 1861–65 was 4,661, or 12 per 100,000 inhabitants; for the years 1871–75, 5,276, or 15 per 100,000 inhabitants; for the years 1881–85, 7,339, or 19 per 100,000; and for the years 1886–90 the yearly average was 8,226, or 21 per 100,000.

OUR PARIS LETTER.

(From our Special Correspondent.)

ACCIDENTS CAUSED BY SERUM-THERAPY — SERUMPATHIE IN CANCER—OPENING OF THE COURSE OF MEDICINE AT THE COLLÉGE DE FRANCE, ETC.

PARIS, May 10, 1895.

SERUMPATHIE, which has hitherto deserved so well of the profession, is, it seems, not always free from accident and danger; nevertheless thousands of cases have been treated by injections of serum since the discovery of the method by Behring and Roux. It has now fallen to Dr. Romniciano, of Bucharest, to publish two observations of accidents caused by this treatment in stridulant laryngitis resembling croup. They are sufficiently interesting to merit the attention of the profession in the United States, and are briefly as follows:

A child was affected with fits of coughing, suffocation, and croupal tirage, accompanied by a slight redness at the back of the throat; temperature, 38.5° C. The next day cough and tirage were less, with mucous sibilant râles in the chest; no trace of false membranes when a first injection of serum was given. The third day (forty-eight hours after the injection of serum) bilious vomiting, eruption resembling urticaria upon the body, polyuria, hæmaturia, and the urine loaded with albumin. Temperature, 38.8° C. Treatment: Mixture of chloroform water with muriate of cocaine and sirup of ether: suppositories of quinine and dry cupping over the lumbar region. The urticaria and hæmaturia lasted two days; the temperature, oscillating between 38.8° and 39.2° C., only fell to the normal one week after the injection, in spite of the daily exhibition of bromohydrate of quinine.

The second case was that of a boy five years of age, suddenly seized with croupal cough, laryngeal tirage, aphonia, and upon the tonsils patches of diphtheritic appearance, in which the bacteriological examination revealed the presence of numerous streptociques, cocci, and bacteria having some analogy to those of Loeffler. A local treatment was instituted, painting with salicylated glycerine, phenol spray, and for general treatment quinine per orem and an injection of serum. The next day, temperature normal; four days later, cured. Two weeks after, pains in the haunches; temperature, 38° C. Salicylate of soda was prescribed for what appeared to be the beginning of an attack of articular rheumatism.

The next evening less pain, but a temperature of 39° C. and a general rubéoliforme eruption. The diagnosis of measles is made. However, the temperature remains at 39° C., the patient coughing little; no redness of the palate, and after rubbing the skin with the hand apparition of patches of urticaria; nothing in the urine.

The temperature rises that same day to 39.4°, then to 39.8° C.; the patches of urticaria extend. Tremblings in the limbs, trismus, and vomiting are observed. Some hours afterward the rubéoliforme eruption pales, but the urticaria persists; then everything disappears except a slight redness around the point where the injection was made and great exhaustion of the child.

Such clinical facts are fortunately rare, but as the treatment by injections of serum becomes more general they become more frequent, and it is quite certain that in the pathogeny of their complications the rôle of the serum was an active one.

As an offset to this we note that Drs. Richet and Héricourt consider serumpathie equally applicable to microbian and infectious diseases generally, notably to cancer. A woman in the service of Professor Térrier, suffering from a fibrosarcomatous tumor adherent to the sixth, seventh, and eighth ribs, was treated by injections of serum. The growth, which was certainly of a cancerous nature (*recidive* on the cicatrix of a former operation), was ameliorated and cured by the injections.

The second case was in the service of Dr. Reclur at the Hôpital de la Pitié. Diagnosis, cancer of the stomach, and treated in the same manner; diminution of the growth, which finally became imperceptible as an isolated tumor.

Drs. Richet and Héricourt see in those two cases a proof that the cure of cancer has been obtained by the anticancerous serum. Notwithstanding such eminent authorities as all the gentlemen concerned are, subsequent clinical facts will be necessary to justify any such conclusion.

Professor D'Arsonval took possession of the chair of medicine on May 1st at the Collége de France. The audience vigorously applauded the distinguished professor, who will continue to study the physiological and therapeutic effects of the electric current, and give the results of his researches to his class and the profession at large. The aperiodical galvanometer is his latest discovery, and now universally used for fine work. He is at present giving considerable attention to alternating currents of the highest possible frequency.

ON THE PHYSIOLOGICAL ACTION OF PERIODIC INDUCED CURRENTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I would like to say in reply to Dr. Rockwell's letter, in your issue of May 4th, criticising my article upon the "Action of Periodic Induced Currents," etc., that up to 1889 upon my return from Europe there was not a satisfactory induction apparatus made in this country, and, furthermore, there was no suggestion to guide the manufacturer in the construction of such apparatus which would be suitable in every respect for the physician. At that time the best fine-wire coil made in this country was wound with No. 32 wire, and contained only about six hundred yards. Finding, by actual experiment with this and other forms of induction apparatus in the market, that they were unsatisfactory for my purpose, I experimented with coils of different sizes and lengths of wire, and finally suggested a combination of coils or windings which would be suitable for all purposes where induction currents were employed. The results of my experiments were set forth in the form of a suggestion for the manufacture of such apparatus in an article entitled "The Action of the Faradic Current in Gynecology," which was read at the first annual meeting of the American Electro-Therapeutic Association, held in Philadelphia, in September, 1891, and published in the *Times and Register* November 7, 1891. In this paper I made a suggestion also that a rheostat or controller be placed in the circuit of the generating cells which supplies the primary, as the best manner of governing and controlling the current during its application. No such suggestion had been made up to this time, nor had the combinations of coils therein suggested ever been approximated. The suggestion made in that paper was that one coil be composed of No. 36 wire, containing 1,500 yards, divided so as to give a current from three lengths of wire, viz., 1,500, 1,000, and 500 yards. Another coil was to be wound with No. 32 wire, containing 800 yards, so divided as to give three different lengths of wire, viz., 800 yards (full length), 500, and 300 yards. There was to be a third coil composed of No. 22 wire, 250 yards long, and a fourth coil composed of No. 18 wire, 100 yards long. The same combinations of coils will be found described also in my book "The Electro-Therapeutics of Gynecology," published by George S. Davis, Detroit, in 1892.

It would appear from Dr. Rockwell's letter that I was appropriating what he seems to feel was a suggestion made by him. A certain manufacturer in this city devised, many years ago, what was then an improved faradic apparatus which I employed prior to the time referred to above, and found very unsatisfac-

tory because it did not produce the desired effect for my class of work, and its construction was protected by patents.

I will say further, that this same manufacturer asked my permission, about two and a half years ago, to wind upon one spool all the different lengths and sizes of wire, as I had suggested, arranging them so as to give the same lengths and the same results, stating that his reason for desiring to construct an apparatus in this manner was that it would make it more compact and convenient. Permission was granted him upon condition that he would only continue its manufacture if I found the results derived therefrom were as satisfactory as with my apparatus as originally constructed with interchangeable coils. After careful experiment I have found that this arrangement is satisfactory. A cut of this apparatus appeared with my recent paper.

If Dr. Rockwell described in the *New York Medical Journal* of May 13, 1893, and August 18, 1894, "the only improvements that have been made in the construction of these admirable coils," it seems evident that he must have taken his suggestion from my article referred to above, which was published in 1891.

A. H. GOELET, M.D.

May 4, 1895.

AN UNSUCCESSFUL MALPRACTICE SUIT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: As I have just experienced all the anxieties and fears incident to a suit for malpractice, and carried it to a successful issue, and believing that any injurious effect to the profession or myself will be best met by the widest publicity, I herewith append details of the case. The patient was an old rheumatic subject whom I had attended for two or three years at various times, and was probably never free from pain.

June 3, 1891, I was called to attend Mrs. Annie E. Harris, of Dunton, who was suffering from muscular rheumatic pain in the left leg of sufficient severity to confine her to bed. I prescribed for her and called the next day, when she was able to come down-stairs and get about in a rolling-chair. At the next visit, June 7th, I found her again in bed suffering quite severe pain. I was told that she had struck her heel against the rolling-chair and had been compelled to go to bed because of the great amount of pain occasioned thereby.

I examined the limb, could find no evidence of injury except a tender point below the middle of the tibia which was painful on movement and when the heel was pressed against.

I visited her again on the 10th, 13th, and 17th, at which time she was going about in her rolling-chair as before. My visits were three weekly until July 24th, when my attendance ceased.

There had been gradual improvement right along, and at the time of my last visit she was able to go about the house by pushing a chair in front of her, using the back for a support. Could go up and down stairs with assistance. Improvement still continued, and a little later she could walk about the grounds.

During August she walked to the railroad station a number of times,[1] went to the city shopping, and in the latter part of August or early September went to Boston on a visit, where she remained until the following spring. While there she spent a number of weeks in a water-cure establishment and was treated *secundum artem*.

After returning home she was treated by a number of physicians, and was finally seen by Dr. Jarvis S. Wight, who, upon examination, found a solution of continuity in the left tibia with the bone-tissue very much softened. Suspecting malignant disease he advised amputation, which was accepted, and the leg was removed at the knee. The entire bone was softened and diseased, and at the point of separation the bony plate was thin as ordinary writing paper. There was erosion of the lower end of the femur, and evidence of beginning disease in the opposite limb.

[1] Distance about a quarter of a mile.

In July, 1894, I was served with a summons and complaint in a suit for malpractice, damages being laid at $25,000.

The plaintiff alleged that at the time of striking her heel during my attendance in 1891 she sustained a fracture of the left leg, which I failed to recognize or treat properly, and because of its non-union and my neglect the condition was produced for which her leg was amputated.

The case came up for a hearing before Judge Bartlett in the Supreme Court at Long Island City, January 8, 1895. We were ready and anxious for trial, but were disappointed. On motion of plaintiff's attorneys, Brooke, O'Sullivan, and Brooke, accompanied by an affidavit of the attending physician that the lady was suffering from acute rheumatism and unable to appear, it went over for the term.

It was again on the calendar for April, before Judge Barnard, and was called for trial April 17, 1895. Counsel on the other side tried the same dodge as before, but failed, their motion was denied and case ordered on trial. Upon their refusal to comply, and at the request of my counsel, the case was dismissed with costs and an extra allowance of $500 for counsel fees—being a judgment in my favor of something over six hundred dollars.

To my call for aid, my friends responded nobly, and I desire publicly to thank the gentlemen who stood by me in my time of trouble—Doctors Jarvis S. Wight, George R. Fowler, Walter B. Chase, Jerome Walker, Arnold W. Catlin, of Brooklyn, and Louis N. Lanehart, of Hempstead. For the able management of my defence, which was invincible, all credit is due to my attorney, Henry A. Monfort, Esq., of Jamaica, N. Y.

The thanks of the medical profession are due Judge Joseph F. Barnard for his eminently just and summary disposal of the case.

SAMUEL HENDRICKSON, M.D.

JAMAICA, N. Y.

New Instruments.

A LIGATURE STERILIZER WITH A THERMOSTAT.

BY V. P. BLAIR, M.D.,

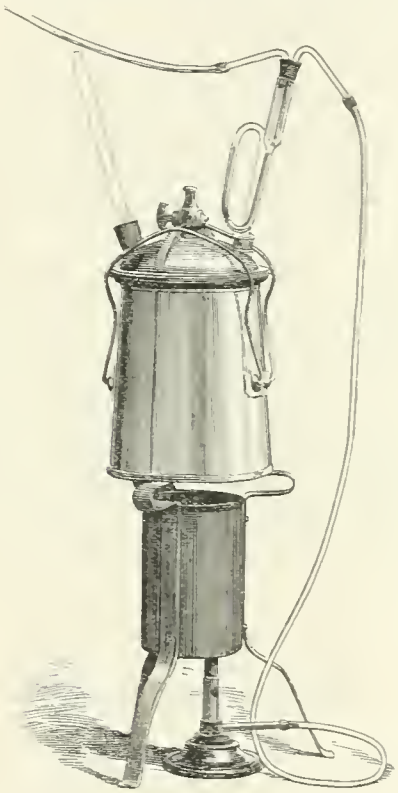
ST. LOUIS, MO.

THE following is a brief description of a sterilizer, or digester, in which any fluid for the preparation of catgut may be kept at, above, or below its boiling-point for any length of time with safety, without attention, without the slightest waste of fluid or fuel, and without that very objectionable feature, the necessity for the condensation of vapor. The latter point was the object of the experiments of which the following is the practical result.

The principle involved is that the pressure of a given volume of gas, at a given temperature, in a given space, is constant. Inversely we have the temperature of this given volume of gas, in the same space, at the given pressure, constant. Here we have a constant and direct ratio between pressure and temperature. This fact is utilized in substituting pressure for temperature in the manipulation of a thermostat.

In a closed cylinder the pressure due to the expansion of a vaporized fluid, or the heated air above this fluid, in forcing down one column of mercury in a U tube, raises the other, which, acting in a thermostat, maintains an exact relation between the flow of gas and the pressure. This idea will be developed more clearly in the description which follows.

The apparatus which the cut illustrates consists of an air-tight cylinder, a tripod, a Bunsen burner, a thermometer, a stop-cock, and a thermostat with a U tube attached. The cylinder, or boiler, is of sheet copper (six inches high), with a heavy brass flange around the opening, and ground flat upon the upper surface, upon which the cap rests. The cap is of heavy (⅛ inch) sheet brass, beaten to a dome shape, and with the under surface of the flared edge ground flat and exactly corresponding to the flange of the boiler. Between these a rubber ring is inserted for packing, while pressure is obtained by brass loops attached to the boiler and riding over inclines on the cap. This makes an air-tight joint, which is absolutely necessary to the carrying out of the scheme. The cap has two holes with flanges for the reception of perforated rubber stoppers and is fitted with a stop-cock. Into these stoppers are inserted the thermometer and thermostat.



The thermostat consists of a small, heavy glass tube, doubly bent upon itself, with the lower end open and the upper end expanding, for the extent of two inches, to several times its calibre, and closed with a doubly perforated stopper. Into these openings enter two L tubes, one plain and the other (the longer) drawn to a fine opening, cut off obliquely, and having a capillary opening in the side. The lower bend of the tube and the two portions leading to it are filled with mercury. The lower free end is inserted into the perforated stopper in the cap of the boiler. The action of this will be explained presently.

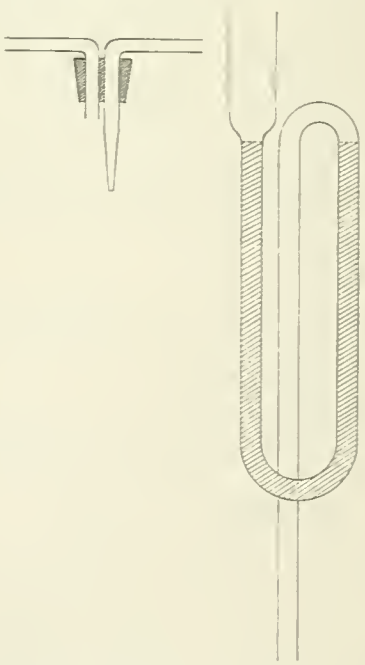
An ordinary Reichert's thermostat, with the tube bent as above described, and the lower end opened, will answer perfectly. The stand is an ordinary tripod: the Bunsen burner is also standard, but has a small piece of wire gauze inserted into the upper end to prevent the flame from descending to the base—this is important. The distance between the upper end of the burner and under surface of the boiler should be at least four inches. The several parts are placed in position as represented in the cut. One of the L tubes running into the upper end of the thermostat is connected with the gas-tap, the other to the Bunsen burner by means of rubber tubes, and the burner is lighted.

Now as long as the stop-cock is open the gas passes freely in and out of the thermostat without any interruption, and the temperature in the boiler will continue to rise, as indicated by the thermometer, until the boiling point of the fluid is reached. If, at the boiling-point, or at any point between that and the temperature of the surrounding atmosphere, the stop-cock is closed, a change at once takes place; the boiler is rendered air-tight, the pressure developed by the expansion of the vapor or air contained, forces up the mercury in the thermostat until it comes in contact with the oblique opening in the L tube and restricts the flow of gas. By this means a proportion between the flow of gas and the pressure is maintained, and a constant temperature is the result.

Now, if the arms of the U tube are long, say eight inches, and they are only filled to the height of five inches, then, when the mercury reaches the cut-off tube, there will be a difference of six inches between the levels of the columns. A six-inch column of mercury means, roughly, a little less than three pounds pressure, and, in this case, the temperature will rise a definite amount after the stop-cock is turned. Thus the fluid may be maintained above its boiling-point. If, on the other hand, it is so arranged that the difference between the two levels is slight, then very little pressure is required to interfere with the flow of gas and the temperature at which the stop-cock was turned will be the result.

When it is desired to discontinue the process, the cock is first opened and then the gas shut off; if this precaution is neglected, the contraction of the vapor will draw the mercury into the boiler.

If the capillary opening in the side of the cut-off tube is too large it will allow enough gas to pass to keep the fluid boiling, regardless of the fact that the lower opening is closed by the mercury. In this case the opening must be made small, or a sand-bath inserted between the boiler and the tube. The latter precaution will be of use when the fluid used is ether; also, when ether is used, cork or fibre packing and stoppers must be employed.



The sterilizer represented was made by Messrs. Holekamp, Grady & Moore, of St. Louis. A perfectly satisfactory one can be made, as the original model was, of a water-bath and a Mason jar, with a stop-cock, a thermostat, and a thermometer inserted into the lid by means of corks and flanges obtained from ordinary ether cans.

This apparatus has been in use for about six months and has given perfect satisfaction. The only incident worth mentioning that has occurred, served to demon-

strate that this thermostat is also a perfect safety valve. While in use in a hospital here a new cut-off tube, with too large an opening in the side, had been inserted into the thermostat; the alcohol continued to boil regardless of the fact that the lower opening was closed by the mercury. When the nurse who was operating it saw this, she became frightened and fled, expecting the roof to follow her. After some time had passed and nothing startling had happened, curiosity overcame the better part of valor. She returned and found the boiler cold, the light out, and the flow of gas completely obstructed by the mercury which had been forced out of the thermostat into the supply-tube.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 18, 1895.

	Cases.	Deaths.
Tuberculosis	94	101
Typhoid fever	6	2
Scarlet fever	63	13
Cerebro-spinal meningitis	1	3
Measles	236	20
Diphtheria	239	36

The Day of the Specialist.—

"Two of a trade can never agree,"
The proverb said of old;
And never a doctor could there be found
His brethren to uphold.
But now they dwell in harmony,
And I'll tell you how 'tis done;
The doctors have split their trade, d'ye see,
There's a slice for every one!

Chorus:

It takes nine doctors to cure a man,
Tho' a ninth of a man he be!

The winter winds have harmed your throat,
You must go to Dr. B.,
"Your stomach is wrong," he calmly says,
And passes you to C.
You mention to C. that pain in your eye
That worries you night and day.
"An oculist's case," he quick replies,
"Just call upon Dr. J."

Too much Burgundy has blossomed out
In the joint of your great toe;
Now where is H., so famed in gout?
To him you must swiftly go.
And when with doctors and bills you're vexed
Till all your nerves succumb,
To minister to a mind perplexed,
Another M.D. must come!

At last you're near your latest breath,
You find yourself laid low;
The faculty are in at the death,
To give you leave to go.
But what's the matter among them all,
They can't exactly tell.
For "diagnosis," who but X.
Can answer the question well?

And now life's fitful fever is cured
By a greater doctor still;
The patient is sleeping well at last,
The heirs have read the will.
But e'en in his tomb, his friends report
A specialist's care he'll need.
The "Alienist" Z. must appear in court
Lest his cranky bequest succeed.

—*The Pittsburg Post.*

Professor Helmholtz's Library has been bought by direction of Chancellor von Hohenlohe for the Imperial Institute of Technical Physics in Berlin.

Compulsory Vaccination.—Dr. Quine, of Chicago, in a paper read before the Illinois State Medical Society, reminded his hearers that vaccination was introduced to the attention of the medical profession by Edward Jenner, in 1798, as the result of investigations which extended over a period of twenty years. During the century preceding, according to the estimates of authoritative writers and statisticians, small-pox, "the most terrible of all the ministers of death," destroyed in Europe alone fifty million human lives. Five hundred thousand deaths every year from the most loathsome pestilence known to man; thirteen hundred deaths every day, nearly a death every minute for a hundred years. If it be true, as is believed by enlightened people, that universal vaccination and revaccination, efficiently done, will put an end to all this desolation and horror from epidemics of small-pox, and finally eradicate the disease altogether, it would appear that the discoverer of vaccination is the greatest benefactor that mankind has known. Alexander was great. Cæsar was great. Hannibal was great. Napoleon was great. They were all great—as destroyers. What have they done? What have all the kings and potentates and warriors of earth done, in comparison with one member of the medical profession in the direction of adding to the sum total of human happiness and human life? Are such conceptions of the possibilities of vaccination an idle dream?

Increase of Drunkenness in France.—The increase of drunkenness is attracting attention among sociologists, legislators, and medical men in France. At the recent Scientific Congress at Caen this question occupied an important place in the discussion. At a special congress of the Ligue Contre l'Immoralité Publique, held at Lyons, the repression of alcoholic intemperance was one of the principal subjects under consideration. Dr. Legraine, chief physician to the Asile de Ville Evrard, read a remarkable report, in which he said that drunkenness is leading France to its ruin. Dr. Pierret, chief physician of the Brou Asylum, and Clinical Professor of Mental Diseases, treated the question of what he terms "unconscious drunkards" who are never drunk, but daily drink more alcohol than the animal economy can tolerate. Dr. Motet minutely described the morbid conditions resulting from an abuse of alcohol, in most instances leading to crime. Dr. Rey, chief physician of the Marseilles Lunatic Asylum, stated that Marseilles, which was formerly remarkable for sobriety, is now no longer entitled to this distinction. Formerly one asylum was sufficient for four departments—the Bouches du Rhône, Var, Gard, and Corse; now it scarcely suffices for the needs of the Marseilles population. There are three hundred children in the City School feeble in mind and infirm in body, who are unable to derive benefit from the education given them. There are as many more children whom the school cannot take. Dr. Rey concluded by saying that, if the evil is not checked, he fears France will become a prey to cretinism.

The Absorption of Odors by Milk.—Dr. Parville relates some facts upon this subject. If a can of milk is placed near an open vessel containing turpentine, the smell of turpentine is soon communicated to the milk. The same result occurs as regards tobacco, paraffin, asafœtida, camphor, and many other strong-smelling substances. Milk should also be kept at a distance from every volatile substance, and milk which has stood in sick-chambers should never be drunk. The power of milk to disguise the taste of drugs—as potassium iodide, opium, salicylate, etc.—is well known.—*Gaillard's Medical Journal.*

The Blood in Melancholia.—From a study of thirty-five cases, Dr. Whitmore Steele concludes that in melancholia, acute and chronic, there is a marked deficiency in the number of hæmacytes, and that the

percentage of hæmaglobin is reduced in like proportion. A number of the cases showing crenation of the hæmacytes at first are found much less crenated after tonic treatment. Tonic treatment is markedly efficacious in this disorder. Iron alone, or with quinine and strychnine, seems equally effective. Although melancholia may not be caused by impoverished blood *per se*, this condition almost invariably exists, and in a large majority of cases improvement of the mental symptoms is coincident with improvement in the general health and in the quality of the blood.—*American Journal of Insanity*.

Children of Young Mothers.—In a paper read before the Congress of Hygiene at Budapest, Professor Körösi, the well-known statistician, stated that the proportion of deaths among children from weakly constitutions, or maladies traceable to the mother, was twice as large among the children of mothers under twenty as among the children of mothers over thirty, upon a comparison of several thousand cases.

The Status of Ether in Germany.—Bruns (*Berlin Klin. Woch.*, No. 51, 1894), in commenting upon the steadily increasing popularity of ether in Germany—a popularity based on statistical study which shows how much safer this agent is than chloroform—calls attention to the fact that there is a beginning reaction in favor of the more dangerous agent on the part of a few surgeons, these men holding that, although Gurlt's statistics conclusively prove that the immediate danger of ether is many times less than that of chloroform, the remote danger is greater when ether is administered, and that from broncho-pneumonia entirely due to the irritating effect of ether vapor upon the lungs, patients frequently perish who would have been saved had chloroform been employed. Thus, Czerny says that he frequently saw light cases of bronchitis and emphysema after ether narcosis. These usually cleared up quickly, but sometimes ran into serious bronchitis and bronchorrhœa, and in some cases even into severe broncho-pneumonia. This last complication occurred in a number of patients who could not expectorate the mucus which accumulated in the throat because abdominal operations rendered coughing extremely painful. He states that he lost two patients on the eighth day from this cause, both these patients being entirely free from bronchitis before operation and the wound running a sterile course. Mikulicz, after a six months' trial of ether, abandoned it, because he observed a number of light cases of bronchitis and two cases of pneumonia. Poppert has described a case of ether death due to œdema of the lungs, and has collected six other cases in which death occurred following lung congestion after etherization. Poppert ascribes all these deaths directly to the ether, and comes to the conclusion that if statistics were collected in which all the late effects rightly belonging to this agent were included, it would be found to be twice as dangerous as chloroform.—*Therapeutic Gazette*.

The Premium on Quackery.—Medical science is sadly hampered by the crude theories of the masses. Far as it lays behind other departments of science it dare not move forward as fast as it could or would if the public would let it. No doctor dare do for his patients the best he might because he knows it would mean instant dismissal from the case. A premium is set upon quackery by even well-educated men and women. The most successful doctors are those who take more pains to treat the friends of the sick than they do to cure their patients. To please the well is the secret of success in medical practice. If it was possible to determine the proportion of successes to failures in the treatment of the sick by each medical man, the world would open its eyes in astonishment. It would be found that those whose patients most frequently recover are by no means the ones with the largest practice or who can command the largest fees. He is the most successful one whose personal appearance is pleasing, who has the greatest ability in appearing to agree with influential friends concerning the nature of the disease and the line of treatment. He must espouse their crudest notions and do nothing to shock their prejudices. Where his judgment tells him that nothing should be done further than establishing hygienic conditions he must pander to their folly and write a prescription. He always does the best he dare for the sufferers, but the amount of benefit he can bestow varies with the violence and character of the prejudices he has to meet. A man whose nature will not permit him to waver from what he knows to be for the best interests of his patients, is constantly the subject of adverse criticism and doubt. Where success promptly crowns his efforts he gets some praise. Where there is delay and no prompt signs of gain he is usually dismissed amid disrespectful criticism from those he has failed to please.—Dr. Albert S. Ashmead, in *Pop. Sci. News*.

The Governor of New Hampshire has vetoed a bill appropriating $100,000 to be used in preventing the spread of tuberculosis among cattle. The disease is said to have prevailed to an unusual extent during the past year.

THE DYNAMICS OF HEREDITY.

By HERMAN GASSER, M.D.,

PLATTEVILLE, WIS.

In studying the forces we call heredity it will be presumed that the general principle of the conservation of energy is so completely established in the various departments of science that it may be called a law. With this general order in the world, the conception we have of life must be in harmony. The complex and complicated forces of the matter of which the organism is composed must be in an exceedingly unstable equilibrium, continually undergoing changes. It is this continuity of change or reaction and adjustment of the forces of the organism, with the external forces, that constitutes the phenomena we call life. That it is not as Foster says "a thing or body of a certain definite chemical composition, but matter undergoing a series of changes." Life as we observe it is hence only the name for the strife, or reaction, between the internal and external forces, an expression of the chemico-physical display of energy in continuity, and it is complete in proportion that the adjustment for continuing is complete. We find that an organism is a continuous and ever-changing mass of material forces. That every change in stimuli necessitates change in the organism with new adjustments. It is this adjustment of the forces in the organism that makes development and evolution possible.

The chemist in the study of the forces and energy of the elementary matter and their relations or reactions according to fixed laws has evolved many organic substances, and from the insight he has attained in their construction now has no hesitancy in stating that "there is little doubt that eventually the synthesis of even the most complex organic bodies, such as albumin, will be possible," the empirical composition of which is C_{24} H_{38} N_6 O_7 plus a trace of sulphur. Albumin is capable of existing in a great many isomeric forms, with slightly varying composition and properties. This is what we would expect in the evolution of albumin, for the environing conditions in different places and at different times would be slightly changed. Of the early period of our earth's existence, when it was still in its infancy, in that "Laurentian sea that existed before geologically recorded time," when physical and chemical conditions and changes of environment for complex chemical compounds existed that cannot be recalled, we can only have a glimpse by the aid of our imagination through the geological mind's eye, and by the assistance of the modern chemical laboratory where by indirect methods and by substitution we may open the little wicket to the condition of those early times. These albuminoids as they were first evolved by modification upon modification of the simpler aggregates of elementary compounds, with increasing complexity and instability, are inorganic compounds, no matter whether made in the early world or modern laboratory. There is not distinguishable a particle of the evidence we call life. No continuity of inner with outer relations, no growth, reproduction, or death. The energy of their composition is the display of the different forces that express the energy of the elements and their reaction on each other in combination. This albumin might satisfy the hunger of animals although only an "organic substance," but thereby demonstrating that the substance of organic beings and the organic substance built up synthetically by the chemist out of inorganic matter are all one and the same.

With all the skill and knowledge of the modern chemist, he cannot, except in his "mind's eye," like a plant, build up from carbonic acid, water, and nitrates carbohydrates, fat, and albumin, but most of them with some skill and great pleasure use up the manufactured products of the plants to form carbonic acid, water, and nitrates. It must be remembered, however, that "the power of forming organic combinations out of inorganic elements is not wholly wanting in the animal organism, although it is in the plant organism that its most favorable conditions are found."

That an albuminoid is highly complex and unstable, easily affected by the multiplicity of forces, is testified to by all experience. In it we find a wonderful combination of forces, the motions of which, while powerful and far-reaching, are so delicate, that with our finest senses we cannot sensate them, and constructive thought is only faintly realized by the aid of the imagination. It is the incomprehensible reality in the sense of the inscrutable forces with which we are oppressed, and when we strive to follow them in our thoughts into the ever-changing infinity of space, and find them but the web and woof of the invisible Power, we can exclaim, with Goethe, that "man is not born to solve, but only to find out where the problems begin." The molecular structure of albuminoids, like that of protoplasm, "is a complex whirl, an intricate dance" that can only be studied in harmony with modern physics, and by inference with the "mind's eye" follow the deductions of experiment into the more intricate and finer actions of molecular motion.

Let us follow this viscous watery albuminoid, as it existed in slightly varying forms and properties in the early condition of the earth's existence, when physical and chemical changes were going on with much greater rapidity than now, and note the effects the forces of the environment must have on a compound of such unstable equilibrium, distributed over the different portions of the earth, and coming in contact with the never-ceasing and multitudinous forces of wonderful constancy. Every reaction must necessarily be of a chemical and physical nature. The forces of light and heat, the daily and yearly changes of temperature, the effects of pressure, gravitation, wind, and wave, the osmotic action and chemical changes within itself, the many other forces almost infinite in variety through their combinations, for countless ages must make it still more complex. The constant and regular forces, like the sun's rays, by producing different degrees of temperature would cause currents in the medium. So the persistent pulses of the various forces would have a tendency to break up the continuity of the mass after the manner of cracking a hard-shelled nut by steady, uniform, and persistent blows, until it finally disintegrates, or the shaft of the steam-engine, that by the constant pulses passing through it becomes granular, and assumes a polar equilibrium. This breaking up of the mass into small particles by the splitting and disintegrating forces would make a change in the reaction of the forces. They would not be transmitted in the same manner. Instead of passing along the lines or paths of previous motions,

more of the energy would be expended on the little masses, for their positions would be changed and their resistance naturally would become greater. The various forces would cause them to impinge one upon another. This constant stimuli of contact would differentiate the external portion into a protective layer. The external layer becoming a little denser and firmer would produce a tendency to transmit the forces through the diameter of the mass, and from all directions the motions would converge centripetally. The forces similar in kind and constancy for geologic periods of time would make changes in the albuminoid masses. The lines of transit would become differentiated, would become easier, for the forces would go along the lines of previous motions or least resistance. The lines of transit becoming more permeable in the masses, they would more readily be affected by the molecular pulses, causing new adjustments and chemical changes. As all the reactions have a tendency to converge centripetally we would there find the maximum of changes and organization, or the nucleus with a more complex chemical composition. As each of the forces is transmitted along the established transit lines there would be a tendency to co-ordinate the motions by a more complex organization for distribution in the mass. The continued repetition and adjustment by increased organization would make the reaction of the stimuli more complex.

The forces acting on the great mass of plastid bodies would not, in all their parts, be alike. There would be a differentiation of the different parts, and they would react on each other. The pressure of wind and wave, of gravitation, and the circulation created by the varying temperature, would possibly force particles of like composition into one another, making again a different and new order of chemico-physical changes, an increased expenditure of energy, with an evolution of heat and giving off carbon dioxide that again would make a disturbance of the inner equilibrium, and start up a circulation or capillarity of its own, to adjust or equilibrate the forces within itself. This increased organization in the cell, with the habit of reacting on the environment in a certain definite though simple and rudimentary way, would be an adjustment to the surroundings. It would harmonize itself with what is going on around it. There would be a selective affinity for certain kinds of substances or food that would impel it in definite directions to secure equilibrium or satisfy its hunger and make the relation with surroundings harmonious and pleasant. While the various specializations of functions and their relations with each other are developing, there is a differentiation of the external surface, of contact, by the assistance of which the selection of things agreeable and avoidance of those of a destructive or inharmonious nature come into existence. So, by slow degrees, the primitive movements would become more rapid, which in turn again enlarges the environment with new stimuli, new reactions of external and internal forces.

The internal structure becoming more complex and assimilating the forces with greater ease and rapidity, the internal and external portions of the plastid cell would not be acted upon alike, and again start up circulating movements of its own to adjust the differences in the molecular structure. The molecular changes within, with loss of oxygen and new arrangement of inner forces, would create an affinity for oxygen-carrying bodies of similar unstable equilibrium. The increase in locomotion, in internal changes, with increased assimilation of surrounding forces, would lead to increased growth. The decomposition resulting from the stimuli of light, heat, and electricity in the cell would be other expressions of the expenditure of energy, and continued by repetition for long periods of time would become better adjusted and organized with increased growth. The amount of oxidation increases, but "the amount of oxygen that can be absorbed from the surrounding medium increases only as the surface of the protoplasm increases. Therefore, in the process of growth the mass would at some time become too great for the amount of oxygen that can be taken in by the surface. The result would be the asphyxiation of the interior part of the protoplasm. In the movements caused by the constant and severe stimulus we may suppose the organism to have extended itself to the utmost in different directions—for the less spherical its shape, the greater its relative surface—until finally the protoplasm parted and segregated into two masses. This is the first step in the multiplication of individuals."[1]

The destructive internal changes must either break up and revert back into their simple elementary composition, or adjust themselves to the surroundings by supplying themselves with the constructive forces for their continuity, and this is accomplished by division. The similarity of the conditions of the segmented masses and their relation to the same permanent stimuli of the environment would cause them to follow the course of development of the parent organization, only it would be just a little faster and easier, being better adapted and adjusted by transmitting the motions along the previous transit lines of motions. This repetition and development, continued for ages of time, tend to perfect the process and eventually become so well established that they would perform in a few moments what it took ages to accumulate in organization in the primitive albuminoid.

There would arrive a time in the growth and adjustment of the cell when the same permanent reactions of the internal with the external forces would develop an organization that would be little short of equilibrium. The changes in the cell would gradually decrease, for the continued sameness of stimuli acting upon it, and the adjustment in organization becoming so perfect, the stimuli of the external forces meet with little or no resistance. Growth is checked and the reaction of the units of the cell diminishes, so that "groups of them partially or wholly detached no longer readily rearrange themselves into the specific form." There is an internal balance of forces preventing a continuance of constructive changes. There is plenty of stored-up energy, but it is neutralized by forces that are equal. The condition of existence for continuance and growth has gone the complete cycle, and unless it finds new adjustments must die. In this unsatisfied condition the cellular organism, finding that the equilibrium of the neighboring cell is unlike its own, makes an effort to absorb it. This commingling of two masses with slightly different rhythms causes the unravelling of the forces of the two along the lines of least resistance, which is the relative adjustment of the combined forces. That the mixing of allied but somewhat different units leads to instability is demonstrated alike in organic and inorganic bodies. That the continuance of the organized cell-like body is dependent on the mixture of different broods, we are well warranted in believing, from the knowledge we have of reproduction in unicellular bodies. Nothing can more clearly illustrate this than the remarkable investigations by Maupas. He showed that by continued fission for a long period of time it gradually grew weaker, then ceased, and finally died, unless they were rejuvenated by other individuals of similar broods, when they would continue in their usual activity.

Throughout the whole series of these cell-organisms, with possibly one or two exceptions, this is the rule. In all animals a little above these simple protozoa male and female reproductive elements exist. The conjugation may be a complete fusion of two entire organisms in some, in others there is an osculation or adhesion of the two oral surfaces with an "immediate transformation of cell contents." The union of the two would be an intermediate form that would create new adjustments and relations, leading in time to more complex organization, increased assimilation and adjustment, with a larger environment. That would

[1] H. B. Orr: Theory of Development and Heredity, p. 112.

again mean new stimuli and changes with increased growth. There would also be a more heterogeneous and longer cycle of reactions, and while performed with greater rapidity, there would be a corresponding increase of time for existence to complete the chain of acquired developmental changes. With the increase of organization and specialization by differentiation of tissues there would be a corresponding differentiation and specialization of conjugation. The longer cycle of reactions in the organism means that the race-plasm does not become mature until the forces of growth and assimilation begin to balance. In the early stages there is a large excess of the molecular constructive forces, the expenditure of which means they are unbalanced. The energy is expended in special definite directions until the organism is developed, when it begins to diminish and finally approximates into a relative equilibrium that "leaves no surplus beyond that which is used up in functions." Each stage is adjusted to the then condition of existence. It unfolds in regular order until it has completed the whole cycle of its existence, "beginning in an ovule, and coming round to an ovule again . . . and after the life of the parent has become potentially renewed in the offspring, the body remains as a cast-off envelope, whose future is but to die."[1]

In following the "persistence of forces" and the continuity of their effects in the effort to reach, but never quite reaching, equilibrium, we have roughly and inadequately traced, along the primal law of evolution, that "every cause produces more than one effect, and every effect more than one change," the continuity of effects by adjustments into the mature moving and organized equilibrium of forces that ends in dissolution. Yet "while the individual withers life is more and more," for the true cycle of existence is the mature race-plasm again, that, with proper nutrition or an adjusted favorable environment, reacts on the external forces along the lines of least resistance, or the established series of reactions, and repeats the previous development in regular order from the beginning of its existence. "Each generation begins its life by responding to the customary stimuli that caused the growth of all its ancestors, and when it has finished that round of responses—that is, has attained maturity—it then stands in a new relation to its environment through the changed state of its growth," at which period we would expect changes of growth and variation. This is what really happens, for the newest variations are the last to occur. The evidence from biology, embryology, and palæontology alike shows that such is the order of growth and variation. We find the organism is built up by absorbing energy, that it is a portion of the great body of natural phenomena, resulting, like the formation of our solar system, out of the nebulous mass, from the co ordinating and organizing tendencies of the forces that by a slow and long process is making every reaction a little easier, quicker, and more uniform, from the primitive matter and motion to the highest organized being. What we call heredity is only a shortening of the process of growth by adjustment of the forces in organization, and so doing in a few moments what it took ages to accumulate.

In the amœba the process of fission completes the simple but mature cycle of its existence, when it again responds to the same round of growth. But those germs, adjusted to a wider reaction of forces, must continue in their regular order and proper sequence throughout the whole cycle of the existence of the organization of which they are a part, before they can renew the cycle and aspire to the hope of that immortality in organization by repetition they all instinctively look for. But if there should be no individual posterity, they can console themselves with the thought that soon their individuality will be lost in the great stream of the race by geometrical division.

[1] M. Foster.

At this time in our investigation the question arises, What relation is there between the germ-cells and body-cells? This problem has been for more than a decade the battle-ground of the advocates of the various theories with varying success. If we adhere to the general conclusions herein set forth, our answer must be, None, except the general effects of the aggregate forces on all tissues, such as good and bad habits. This is, in a measure, a concise statement of Weismann's theory of continuity of the germ-plasm and its "isolation" from the functions of the body. His contention as to its distinct nature and isolation from the body-cells has necessarily forced him to accept "natural selection" by congenital variations as the sole and only method of evolution, and has burdened his theory with a host of facts that it cannot assimilate and harmonize. It clearly explains inheritance, but it must assume another relative condition to explain all the processes of evolution. The antagonistic or Lamarckian school "attribute evolution to the hereditary transmission to offspring of changes (acquired variations) caused by environment and habit in the parent," and contend that there is some form of force, like "physiological units" or matter like "gemmules," that connects the body-cells with the germ-cells, or pangenesis. This theory explains evolution, but does not furnish a particle of evidence for heredity.

The position of the two leading schools is clearly and fairly stated by Professor Osborn, himself a Lamarckian, in the following words: "It follows as an unprejudiced conclusion from our present evidence that upon Weismann's principle we can explain inheritance but not evolution, while with Lamarck's principle and Darwin's selection principle we can explain evolution, but not, at present, inheritance. Disprove Lamarck's principle and we must assume that there is some third factor in evolution of which we are now ignorant."

In the very interesting and profound Cartwright Lectures before the Academy of Medicine of New York in 1892, on the "Present Problems in Evolution and Heredity," as published in Vol. 41 of the MEDICAL RECORD, Professor Osborn stated that "the inheritance of definite changes in the somatic cells is also necessary to explain evolution," and then drifts away from the fact and its relation with the Weismann theory, and says: "Therefore there must exist some form of force or matter which connects the activities of the somato-plasm with those of the germ-plasm," that it may cohere with his Lamarckian bent of mind.

The possibilities that are in the germ-cell have a tendency to veil it in mystery, and we are disposed to burden it with potencies that are inconceivable and undemonstrable in the order of nature, and makes it difficult for us to form a conception of it in its relation to histogenesis in terms of chemistry and physics. This minute amount of energy and matter has no peculiar material or molecular structure out of harmony with all the other forms of protoplasm. That a germ-cell has no inherent possibilities of development of its own, but is absolutely dependent on its environment, must be conceded. Unless it receives energy and matter from the outside, it dies. The germ-cell, like every other specialized cell, has a certain definite molecular and material structure with chemico-physical relations, but not the "peculiar" structure of Weismann or Lamarck. Under favorable conditions the germ-cell has the capacity of absorbing energy from the outside world in a definite manner, that causes increase in its growth after the manner of evolution in general. With this increased amount of growth and energy it is changed, with a change of reactions on environment. It is no longer a simple germ-cell, but a mass of energy in continuity, changing every moment of its existence by assimilation of more energy, and each new change means a new adjustment of the forces in constructive organization that is built up out of the forces of the environment to react on the environment. It is simply

the persistence of force in continuity by organization or adjustment. The germ-cell has the power to assimilate energy after its own capacity, but as soon as it enters the first link in the chain of continuity, it is no longer a germ-cell. The specialized cells, like the germ-cells, take up energy, but their relations to the organism cause them to expend it in special definite directions that break up the continuity.

We know from the experiments of Darwin, Dr. Born, and Professor Yung that by special methods of feeding and the influence of different-colored light the average constructive forces of animals may be changed and to a certain extent determine their sex, size, and pigmentation in the skin; that the kind and amount of exercise of the young largely influence their development is recognized by our methods of training and education; that plants and animals look, act, and taste different when brought up under changed conditions of food and environment. Then witness the mechanical adjustments of animals that live in the water, on the surface, and in the air, and we must conclude, with Professor Orr, "that organisms do not become what they are in their adult form by a simple unfolding of their innate energy. Their development, and even life itself, is dependent upon and caused by the never-ceasing action of the forces of their environment."[1] The very instability of the chemical and molecular condition of organisms necessitates movement. There must be a constant interchange of forces between the organism and the external nature for continuity or life. These external forces must be converted into molecular motions within the tissues, each after its own kind. We know too that in the development of embryonic life there is the same order of chemical and physical changes, subject to the same laws of molecular mechanics that apply universally. The fact that there are regions in the body where evolution or change results with varying rapidity, as in the lower portion of the chest and in the foot in man, as pointed out by Professor Osborn, and their adjustment by new relations, habits, and organs, is in itself conclusive that there is in local portions of the organism a tendency to definite acquired variations. From observations like these all must admit, with the Lamarckians, that environment causes variations of growth, but not with them that there is a material connection between the body-cells and germ-cells. These newly acquired variations in the race we find to appear in succeeding generations just a little earlier in the life of the organism, because, by the continued action and reaction, they would tend to become a little better organized and hence easier and earlier. These variations in the local organs of the organism result from the continued repetition of the same order of stimuli. There is an organizing and distributing tendency in the single or special organs with adjustment to the continuity of the whole and the external forces. While there is no individual continuity of local organs there is persistence of specialization as a part in the stream of continuity. The special organs like the special cells expend their energy in a special definite direction, but while unbalanced for repetition their persistence appears again in the established harmony in succeeding generations as a part of the continuity, subject to the same principle that influences continuity in general. It is not a question of the material composition of the germ- or body-cells, but only of the forces which act through them. We are apt to be blinded by the assumed fact that all the powers and relations of the varied forces called heredity are encompassed in the little germ-cell $\frac{1}{250}$ of an inch in diameter.

In the physiological division of labor specialization of function is produced at the expense of the general function. The nerve, muscle, and secreting cells in performing their special functions have special adjustments to the organism, but have lost their general equilibrium to the external forces and hence cannot repeat themselves, and die. When the same round of transformations come around again, the tendency from the preceding generation will influence the local developmental reaction. This inheritance, or better, organizing tendency is necessary, not only to explain evolution but regeneration. It is theoretically improbable and contrary to practical experience that the somatoplasm has any direct connection, or that it impresses itself in a certain definite way on the germ-plasm.

That the germ-cell is simple and of no special material or molecular complexity is evidenced by all investigations. Indeed it must be in the simple and rudimentary first stage of existence to fit it to start with the first phase of growth in the chain of associations worked out of the material forces of the world. In this first stage the changes are alike in all organisms. In the protozoa it is slow, and comprises the whole cycle of existence. As organism becomes more complex, these early changes become more rapid, for they have been most often repeated, and as they near maturity gradually become slower and more uncertain from the same cause. In the fission of an amœba the new amœbæ go through a regular cycle of assimilation and growth before they attain maturity, when they are ready to again repeat the round of transformations. This is just as true in the higher organisms. They must go through the whole cycle of transformations before arriving at maturity of germ-cells. The germ-cells are set apart in the regular order of histogenesis for the special purpose of retaining the primitive condition of existence, and the fact that they do not mature until the growth of the organism is nearly or quite complete is evidence that the accumulation and development around them must go the whole line of continuity before they complete the cycle of their growth. While the general development is going on, the germ-cells multiply into "hundreds of thousands" like themselves, and then grow to maturity. The constructive forces of the general organism and the germ-plasm mature about the same time to general equilibrium.

In some of the plants, and among lower animals, where the specialization of function is not yet highly differentiated, the cells still retain a large share of the general functions, and any part may reproduce a complete new individual. "As we ascend in the animal scale, the power is confined to the reproduction of a lost part," and in the highest is confined to regeneration only. This is what we would expect from the relative order in histogenesis, and "the only logical interpretation of these phenomena is that the hereditary powers are distributed in the entire protoplasm of the organism." In the healing of a wound or regeneration of a limb there is no "pre-existing germ of the condition or member," but they are due to the organizing and distributing power of the cells at the exposed surface. The cells assume the power of regeneration at the expense of specialization for the purpose of self-preservation. The cells revert back toward an amœboid condition and build up along the organizing tendencies, and in the course of repair begin to differentiate again in many instances into their special kinds of tissues, resulting from their varying constructive tendency. This kind of development certainly has no connection with the germ-cells and again shows that the "hereditary" powers of the specialized cells have nothing to do with the germ-plasm. The fact also that there are "hundreds of thousands" of germ-cells makes it equally difficult to translate into thought the connection between each with every part of the organism. We also find that the regenerative power follows along the same general order of development. In the specialized tissue injury means "solution of continuity" from the aggregate of activities, and a "return to the embryonic condition" after the manner described by Stricker.[1]

The arm of a man, says Spencer, buds from the side

A Theory of Development and Heredity, p. 58.

[1] International Encyclopedia of Surgery, vol. i., p. 28.

of the embryo as a tongue-shaped mass of simple, undifferentiated cells. It is the organizing tendency of the forces of these cells that ultimately differentiates into the mature arm. It is not outside the limits of legitimate speculation to say that if, in this embryonic condition, the arm was amputated, it would be regenerated in all its parts, as in the frog and salamander. The body-cells mature and differentiate early, and their special equilibrium is in a great measure dependent on the general equilibrium of the organism. They are out of tune to react on the constant and general forces of the environment, and therefore unfit for development in continuity. They are born to die. Their own specialization kills the continuity. In them, like in the germ-cells, their adjustment is dependent on a definite material and molecular structure. The germ-cells of the different plants and animals, while specialized to begin the process of development after the same simple and rudimentary method, yet have each definite chemical and molecular properties, otherwise species and genera would cross and recross. But the germs of the different species arrive at maturity under the constant change and condition each parent is subject to. The rate or rapidity of reactions must necessarily differ with each species, and as the rhythm or wave-length is unequal and unlike there can be no crossing. They neutralize the continuity by the expenditure of their energy in different directions, and break up the rhythm along definite directions. Each is strung to a different tune. Even in the same species there is variability that is more marked in the union of races brought up under varying conditions. Also in our domestic animals this fact becomes quite prominent. Every union of germ-plasm of the same species implies a rearrangement, a redistribution of matter and motion where the strength of the organizing tendencies of the parents in every part of the developing organism is in conflict, looking for supremacy of expression. Each germ-cell is specialized by the special environment under which it is matured, and while they start the process of development from the same point, the length of their courses and the rapidity of their gaits are very unequal. In some it is indefinite and rudimentary, like the steam in the tea-kettle, in others by proper direction in organization like the steam transmitted through the modern engine to various machines, differentiated into a complex organism. It is all the same force, only expended in certain definite directions, and illustrates the fact that the universe "living and not living is a mechanism, and that, as such, it is explicable on physical principles."

ON THE DIAGNOSIS OF CHRONIC DISORDERS OF THE STOMACH.

By H. BECK, M.D.,

NEW YORK.

The object of this paper is to call attention to the indispensable necessity of a complete and, as far as possible, an exact physical and chemical examination of the stomach and its contents, in order to successfully restore to the physiological state an organ which is daily subjected to manifold dangers, in the shape of thermical, chemical, mechanical, and parasitical irritations.

To the indefatigable researches of Leube, Ewald, Boas, Rosenthal, and others we are indebted that we are at present in a position to determine the nature of the gastric contents, their activity and their digestive power, with as much clearness and certainty as if we had the whole process exhibited before us in a glass vessel. In the presence of doubt, we must by no means consider the modern teachings regarding the diagnosis of chronic gastric diseases as thoroughly exhausted.

In the year 1822 Bush used for the first time a stomach-pump to evacuate the stomach in a poisoning case. With our means at hand, it seems to me an established fact that no diagnosis of any stomach disorder can be considered indisputably correct unless confirmed by chemical and mechanical investigation. It is to be regretted that the stomach-pump enjoys very little popularity in the field of diagnosis, while its use as a therapeutic measure is quite extensive — even very often unjustly and with great disadvantage to the sufferer. After the trying list of drugs is exhausted, and all the acids and ferments, the bitters and alkalies, as well as all possible artificial nutritives—which are very often given without any definite scientific object—have failed to produce any effect, the stomach-pump is brought into use, and the stomach is "washed," without any known purpose or aim.

Let us divide the wide complex of gastric disorders into acute, chronic, primary, and secondary diseases. There is hardly any grave pathological state in the economy without some accompanying gastric symptoms. It is immaterial whether this organ itself undergoes any real pathological change or responds sympathetically to some distant reflex irritation. This apparently resistible organ gets very easily out of order under circumstances which would hardly affect other organs. In childhood this fact is most striking. In many acute infectious diseases the first onset of the malady is ushered in with violent vomiting. Indeed, there are many forms of disease in adult life in which the stomach is very often selected as a centre of action, when in reality there is no immediate derangement of that organ at all; such disorders include the masked forms of malaria, uræmia, etc. But not only acute and subacute, but also chronic diseases—and these rank here first—drag the stomach into copartnership and leave traces in this organ long after the fundamental disease has disappeared. Beside cardiac and organic circulatory disorders, as well as chronic lung and liver affections in which the circulation of the stomach is disturbed, and consequently acts noxiously upon the secretion, and peristalsis—even resulting in grave anatomical changes in the mucous membrane—there is a series of diseases which by their proximity affect the gastric wall, making the latter responsible for the ailment. Thus a past acute or an existing chronic peritonitis, itself very little troublesome to the patients for quite a length of time, may give rise to very serious symptoms by the formation in the pyloric region of short cord- or band-like adhesions, resulting in external constriction of the last-named region. I should say that such a constriction is by far more dangerous than the constriction formed by the cicatrization of the mucous membrane of the pylorus. These are the so-called "symptomatic" or "secondary" stomach diseases, in contradistinction to a large variety of primary gastric affections.

Passing over the acute affections, such as gastritis acuta, gastritis phlegmonosa, gastritis toxica, and, justly or unjustly, gastromalacia, let us divide the remaining list into chronic primary and chronic secondary gastric diseases, denominating as "primary" only those affections in which the cause of the trouble is to be found in the stomach itself, and as "secondary" those in which the cause is located in some distant organ, calling forth some gastric phenomena in the second or third instance, without, however, causing any organic changes. In connection with pulmonary emphysema, I call stomach affections secondary if certain gastric symptoms originate in some changes of circulation in the vena cava inferior without any essential changes in the secretory or motory functions. On the other hand, I shall consider any gastric symptom as a "primary" affection, in case the physiological functions of that secondarily attacked organ sustain some impairment, namely, if peristaltic and especially secretory disorders take place. In such cases the primary pulmonary em-

physema is to me nothing more than a cause of the secondary stomach disorder, as well as an improper diet of long duration would be.

These facts are of great importance in the treatment of chronic stomach diseases. Let us bring the following instances: A patient is suffering from valvular disease of the heart, albumin in the urine without cylindrical casts, eructation, vomiting, anorexia, but with normal acidity of the gastric juice. The autopsy in such a case would reveal nothing but lesions of the heart and consequences of the same in the form of stagnation of the blood. The pathological changes are therefore not to be found in the kidney or stomach, but in the blood-vessels. The symptoms of the first were only secondary phenomena. A patient has valvular disease of the heart, albumin in the urine and cylindrical casts in the same (or hæmaturia), eructation, anorexia, vomiting or hæmatemesis, and diminished or increased acidity of the gastric juice. The autopsy would reveal not only valvular lesions of the heart and changes in the blood-vessels, but also a distinct nephritis, which may have been the result of a long-standing stagnation, or embolism, chronic gastric catarrh, or round ulcer, as a consequence of the altered blood circulation or emboli. In any case the stomach is anatomically changed and consequently primarily affected by the etiological factor—the valvular disease of the heart. For should we examine a kidney or the stomach as above described outside of the body without previously knowing of the existence of any heart disease, we should certainly pronounce the case as nephritis or gastritis chronica.

The first requisite in the proper treatment of stomach disorders is doubtless a correct diagnosis. Only those whose habit it is not to make a diagnosis before determining satisfactorily the exact chemical and mechanical state of the stomach will surely have found out how often mistakes are made in this direction. Very often "neurasthenia" is diagnosticated in case the patient is found to possess a general nervous disposition in connection with his gastric trouble, as though it were an impossibility for anyone to be nervous and to be suffering at the same time from gastric dilatation of a marked degree, or to be neurasthenic as the result of his suffering. If the patient complains of acid eructations alkalies are given unhesitatingly; pepsin and hydrochloric acid in case he complains of "indigestion" are prescribed, as if the occurrence of acid eructations in connection with cancer of the stomach could not simultaneously exist. The following two examples will clearly illustrate how much injustice is done to the sufferer when a diagnosis in stomach diseases is founded merely upon external examination:

A soldier, aged twenty-three, a circus-rider, was admitted to the military hospital in which I served; complained of nausea and burning in the gastric region. His appearance was pale, large boned in construction, but pretty much emaciated. He was examined, starved during several days in the hospital, and after a week it was decided that he was only feigning and ordered discharged from the hospital. On the evening before his discharge he had a severe hemorrhage, which on account of its very acid reaction was traced to the stomach. Two hours later a second and a third and then a fourth hæmatemesis occurred. Thus the feigning soldier proved at once to be suffering from round ulcer of the stomach.

The second case in my experience was a young man twenty-one years of age, of slender structure, anæmic, highly nervous, and an onanist. He had already consulted, as he said, about two dozen physicians, and had read many books regarding his disease. His condition was considered to be a form of sexual neurasthenia and nervous gastric disease. He complained of pain in the cardiac region, which was aggravated after eating, acid eructations, vomiting, and pyrosis. The stomach-pump, however, was not resorted to as an aid to diagnosis. The patient being quite an intelligent young man, I easily succeeded in convincing him of the necessity of an internal examination. I found the following: In the morning nothing could be obtained from the empty stomach. After introducing 200 c.c. of distilled water into the stomach the acidity was $0.6561 = 18$ (normal according to Leube, $0.1642 - 0.4380 = 5 - 12$). After Leube's, test-dinner (a plate of soup, a piece of bread, a steak, and a glass of beer), in four and a half hours $3.2815 = 90$ (normal, $1.5 - 2 = 40 - 56$). After the test-breakfast (a cup of tea and a roll), in one hour $2.2599 = 62$ (normal $1.095 - 1.46 = 30 - 50$). One gramme of salol was administered and no reaction followed in the urine after one and a half hours. In view of these points and of his localized pain my diagnosis was ulcus ventriculi rotundum. I pointed out the situation to the patient, but lost track of him. Some seven or eight months later I was called to see him. I found my man in a pool of blood recently vomited, three hemorrhages having occurred the same morning. I learned also that during the preceding eight months the patient had consulted at various times different physicians, and his statement that he was suffering from ulcer of the stomach was ridiculed.

A scientific diagnosis in the realm of stomach diseases is not an easy thing. First, because not every patient is easily induced to have his stomach washed without having previously used a full stock of powders and torrents of medicine. In the second place a good deal of patience is necessary, on the physician's part, to evacuate the stomach for at least three times: 1, in its empty state; 2, after test-breakfast; 3, after test-dinner; to filter the contents and then to make the chemical and physical examinations. The former difficulty I have learned to overcome in most cases by introducing the stomach-pump without letting the patient know the nature of the instrument and its purpose. In doing this I am convinced that the patient, in his ignorance, considering the rubber tube a harmless thing, will swallow the same more readily than one who knows all about the procedure. The first step being accomplished and the patient being convinced that the operation is not such a big bugbear as he might have thought, it is an easy matter to proceed with further examination. Of course, it happens that the tube is afterward brought down with difficulty, but this is easily overcome.

As to the second difficulty patience is necessary. Much would be accomplished in this respect if it were at once determined whether hyperacidia or anacidia of the gastric juice exists. Every vestige of doubt as to whether the disease is of organic or nervous origin would be at once removed. In doubtful cases the physician would be guided in which direction to turn in order to at least not do any harm to his patient. Of course it is not sufficient to use litmus-paper or nitrate of silver for examination, because the former reacts not only with hydrochloric acid, but also with all the acids, and the latter forms precipitate not only with free hydrochloric acid, but acts in the same manner with chlorides. If thus the determination of the total amount of hydrochloric acid in the gastric juice is not necessary and only a proof of its presence is desired, a tropeolin solution (a saturated alcohol etheric solution of tropeoline) and Günzburg reagent (1 part vaniline, 2 parts floroglucin, and 30 parts alcohol) will suffice. A tropeolin solution of yellowish color will produce a cherry-red color in the presence of $0.109\ HCl = 3.0$, by which also the degree of acidity would be approximately determined. The vanilin-floroglucin solution reacts with a very small quaniity of HCl, namely, $0.0091 = 0.25$. An equal amount (2 to 3 drops) of the Günzburg solution and stomach filtrate are placed together in a white porcelain dish and gently heated over a small spirit flame; a delicate rose-red tinge appears at the margin of the liquid in the presence of HCl (at least 0.0091). In this way it is readily established in

practice: 1, whether HCl is present; 2, an approximate determination of the limit between 0.0091 and 0.109 (0.25 and 3.0).

Now the question forces itself upon us: How can an anatomical change of the mucous membrane of the stomach be differentiated from a pure functional disorder, emanating from a nervous source? The secretory neuroses of the stomach occur mostly under the form of increased secretion of HCl; whether neuroses are also encountered with diminished secretion of HCl is not yet certain; it is probable, however, that diminished secretion of HCl does not exist in connection with neuroses of the stomach. The influence of the nervous system upon the secretion of the gastric juice is not known. The innervation of the gastric wall consists of Auerbach's and Meisner's plexus, which, forming independent ganglia, communicate with the terminal filaments of the pneumogastric and sympathetic nerves (plexus cœliacus, solaris, and splanchnic nerve). The influence of these nerves upon the peristalsis of the stomach are well known, and consequently the disturbed functions of motion and sensibility are very easily explained. As to their secretory influence, however, it is only a matter of conjecture by comparison with other glandular organs. The empty stomach, under normal circumstances, does not contain any HCl, or contains only traces of it; the reaction is neutral or even slightly alkaline or slightly acidulous. As soon as some food is introduced the secretion begins over the whole surface of the mucous membrane, which is in no other way explainable than by reflex nervous irritation. In case of increased sensibility of these nerves a scarcely perceptible irritation, under ordinary circumstances, will effect an increased secretion of the gastric juice.

It follows, then, that the examination of a non-irritated, consequently non-digesting, stomach is of importance in diagnosis. Under these circumstances I am inclined to consider the so-called digestive hyperacidia as a symptomatic disorder, having its origin in the nervous over-irritation, while the hypersecretio continua, or, as it is called, gastrorrhœa acida, is to be considered as a prodroma to a chronic acid gastritis. Autopsies of the two named diseases are wanting; and it is no wonder, owing to the fact that digestive hyperacidia never leads to a fatal termination, and the gastrorrhœa acida, even if it terminates in death, shows the lesions of the well-formed chronic catarrh or ulcer of the stomach. Thus, if everything in the empty stomach is found to be in normal state, the stomach complaint is to be considered of a purely nervous nature. Of course the microscope will give us also some information as to whether there is any inflammatory process going on. A *résumé* of all this would include the following conclusions: 1. If the contents in the empty stomach are found to be free from HCl, pepsin, and mucus, the reaction neutral, an anatomical change of the mucous membrane is to be excluded, and consequently the ailment is to be considered a symptom of some indirect or nervous influence. 2. Distinct acid reaction in the empty stomach is conclusive of gastrorrhœa acida, chronic acid catarrh, round ventricular ulcer. 3. Distinct alkaline reaction in the empty stomach is proof of mucous catarrh, atrophic catarrh, or cancer. In all those forms of diseases enumerated under 2 and 3 we find, microscopically, inflammatory products in the shape of exudative white globules, the gastrorrhœa acida not being excluded; it proves that the last-named disease is also an inflammatory process.

In this connection it will not be out of place to say a word about the differential diagnosis of the chronic inflammatory diseases of the mucous membrane of the stomach.

Gastrorrhœa Acida.—In the empty stomach sufficient free HCl to digest albumin; at the height of the digestive act acidity increased even to double that of the empty stomach.

Catarrhus Ventriculi Chronicus Acidus. — In the empty stomach distinct HCl reaction and pepsin as well as milk-curdling ferment; at the height of the digestion acidity not increased or often less than in the empty stomach. The free HCl can be sometimes latent, owing to the neutralization of bile which finds its way into the stomach in a reversed peristaltic manner caused by the irritation of an excess of HCl overflowing into the duodenum.

Ulcus Rotundum gives the same chemical results as the acid catarrh, and the diagnosis is made from the duration of the disease, characteristic burning localized pain, and in two-thirds of all cases hæmatemesis confirms the diagnosis.

Mucous Catarrh.—In the empty stomach a large quantity of mucus, alkaline reaction of the gastric contents during the interval as well as the height of digestion, lack of pepsin, and milk-curdling ferment. Microscopically we find shreds of mucous membrane. Should acid reaction be present, it is due to the formation of lactic acid (to be detected by Ufelman's reagent).

In the Atrophic Catarrh no mucus in the empty stomach is found, but there is alkaline reaction at the height of digestion, lack of pepsin and propepsin, milk-curdling ferment, and pepton. Microscopically no mucous membrane shreds, but masses of bacteria.

Carcinoma Ventriculi is often the result of a mucous catarrh or round ulcer, the symptoms of which predominate at the beginning. Later on, however, the diagnosis is cleared up by the appearance of swelling, hæmatemesis, or occasionally by bringing out through the stomach-tube of some particles of the new growth.

From all this we may conclude that we are justified to diagnosticate "neurosis gastrica" only when no abnormal acid or mucous secretion takes place in the empty stomach, even if it be present at the height of digestion, as in cases of hypersecretio acida on the one hand, and insufficientia secretionis on the other. We may diagnosticate neurosis gastrica when morphological elements, such as inflammatory products, are to be found, or mucous membrane shreds, determined microscopically; also when the general state of nutrition does not sustain any impairment by the existing malady, and furthermore so long as there are no mechanical impediments in the way of alimentary passage, which may result in dilatation of the stomach. Never should the assertion of the patient have too much weight in influencing the diagnosis.

The different forms of stomach neuroses and their character are very easy to recognize; they often reveal themselves to the observer at the first glance. Whether they are motory, sensory, or secretory neuroses the treatment remains the same, viz.: strengthening of the nervous system, occasionally narcotics, neurotics, and psychical relief. Of course, the causes do not often originate in the nerve-centres or peripheral nerve-tracts. A tænia can thus give rise to nervous gastric symptoms without being discovered for months and even requiring years to be finally unmasked. Not less characteristic is the vomitus gravidarum in the first months of pregnancy, which is said to emanate exclusively from nervous reflex irritation. On two occasions I was enabled by means of the stomach-pump to obtain the stomach contents from a pregnant woman suffering from vomitus gravidarum. In both cases I found pronounced catarrhus ventriculi chronicus acidus. I am not certain, however, whether the beginning of the trouble existed prior to pregnancy or not; although, according to the patient's statements, the first symptoms appeared during pregnancy, still lack of subjective symptoms is not sufficient proof of the non-existence of a chronic disease of the stomach. I have seen one of these women since delivery, in whom no examination could be undertaken, as the woman stated she felt quite well, nor has she suffered from any gastric trouble since then.

Before I proceed any further I shall allow myself to allude briefly to the diagnosis of the motory disturbances of the stomach. It must be candidly confessed that the method used for this purpose is very inadequate, and the results obtained in this manner present marked fluctuations. Salol, which is insoluble in the acid medium of the stomach, is supposed to dissolve in the alkaline duodenal contents and split up in the blood into its components, carbolic acid and salicylic acid, and then become excreted by the kidneys in the urine. Can anybody guarantee that the salol is dissolved immediately after passing the pylorus and directly absorbed from the duodenum? Most absorption occurs, as a rule, in the lower portion of the intestines. "On the entrance of the chyme into the duodenum, it is subjected to the influence of the bile and pancreatic juice, which are then poured out, and also to that of the succus entericus. All these secretions have a more or less alkaline reaction, and by their admixture with the gastric chyme its acidity becomes less and less, until at length, at about the middle of the small intestine, the reaction becomes alkaline and continues so as far as the ileo-cœcal valve."[1] Furthermore, the filtering and transudating power of the kidney is different in different individuals. Our object, however, is to learn by this test the time which elapses between the escape of the first and remaining portions of the food from the stomach. Finally there are forms of stomach-diseases which are distinguished by the alkalescence of the stomach contents, being therefore a suitable medium to render the salol soluble in the stomach itself, and these are the diseases especially in which an estimate of the motor function of the stomach is of great importance in regard to diagnosis. It is advisable, after all, in cases where an accurate estimate of the mechanism of the stomach is desired, to resort to the use of the stomach-pump, by means of which the exact time between the introduction of food and its escape from the stomach can be determined.

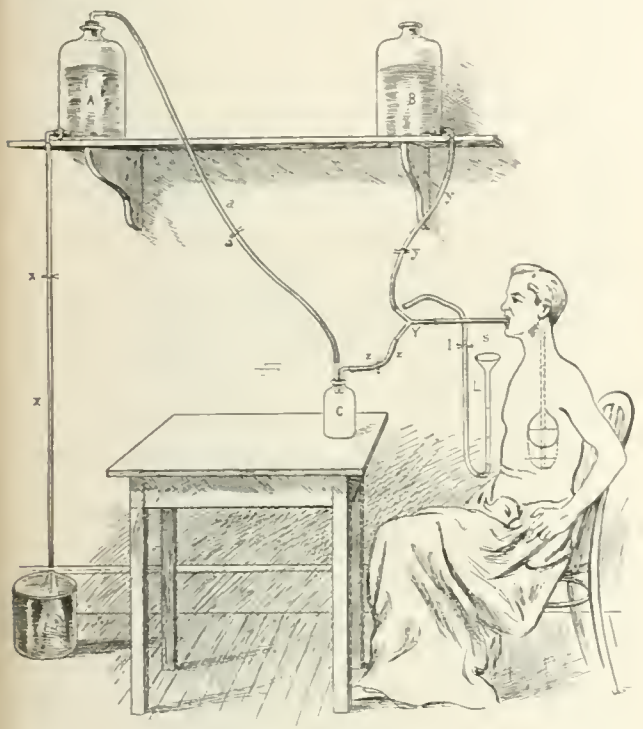
The one subject which receives a step-motherly consideration at the hands of the private practitioner is most decidedly the capacity of the stomach. Every one who takes a warm interest in stomach diseases will have found out that the demarcation of the greater curvature is often attended with invincible difficulties, and it often requires many a sitting in order to ascertain the existence of dilatation of the stomach. Thus a quart or more of the stomach contents may be withdrawn in the morning from the patient's empty stomach and sarcina ventriculi are found, both of which indicate the existence of a gastrectasia, but are in the abstract not sufficient to diagnosticate with certainty a dilatation of the stomach. Palpation is unreliable and percussion is very untrustworthy as a means of investigating the abdominal organs; likewise unreliable is the method of using an olive attached to a silk thread, which is swallowed and said to reach the lower curvature. Were it only possible to exactly determine when the olive touches the lower mucous membrane of the stomach this method might be of value. Less objectionable would be the hard-rubber sound. It is, however, very disagreeable to the patient, and the danger of perforation is present. The other methods include the pouring in of water and the inflation of the stomach with air or gas by the introduction into the stomach of effervescent powders and water. The inexpediency of both these methods is quite apparent, as the excessive weight of the water (sometimes five quarts) or the immoderate expansion of the gas may cause the lower limit of the stomach to descend farther downward, thus producing an artificial dilatation and consequently misrepresenting conditions. Besides these procedures do not always succeed easily; large quantities of water are not always retained in the stomach without reaction, the fluid is mostly regurgitated, and the feeling of tension of only small quantities of gas is so pronounced that a further expansion of the stomach is impossible. If there is also associated some morbid affection of the mucous membrane, as, for instance, atrophy, ulcer, etc., it would not be unprecedented if a hemorrhage or perhaps perforation were the immediate results of this procedure. Concerning the illuminating of the stomach with an Edison lamp, a method first introduced by Einhorn in order to designate through the abdominal wall the size and shape of the stomach, I personally have no experience, but I think that it shares the disadvantage of all the illuminators, namely, that it is too expensive to be in the hands of the general practitioner.

[1] Kirke's Handbook of Physiology.

In order to avoid all inconveniences I endeavored in a rather uncomplicated manner to determine with the greatest possible accuracy the lower limit of the stomach without thereby exposing the patient to a greater danger than the use of an ordinary stomach-pump. The apparatus is constructed upon the basis of the Rosenthal pump—which I use for the investigation of gastric contents—with a modification forming the gastro-meter proper. I wish here to remark that I do not learn by this means the cubic dimensions of the stomach space, but it enables me to determine the longitudinal diameter, namely, the distance from the cardia to the lower curvature, as well as the natural situation of the lower limit of the stomach, without displacing it artificially. As everybody may not be acquainted with the Rosenthal pump, which forms an integral part of this device, I shall describe it briefly and explain its mechanism. It is based on the vacuum principle and consists of the following parts: 1, Two large glass reservoirs measuring about eight quarts each, A and B, placed at an elevation of one yard above the examining-table; 2, one receiving bottle C. The reservoirs A and B have each an open neck near the bottom provided with a rubber cork through which a glass tube passes. Bottle B is uncovered at upper opening; bottle A has in the upper neck a rubber cork through which a short glass tube bent at an angle of 90° passes. The upper and lower glass tubes which leave the bottle A are provided with rubber tubes a and x. Tube x discharges into a vessel near the table. Tube a is connected with a glass tube passing through the rubber cork of the receiving-bottle C, the glass tube not reaching deeper than 1 ctm. into the bottle. The lower neck of bottle B is provided with a rubber cork and a glass tube from which a rubber tube y runs downward. In the cork of bottle C is a second glass tube, which (like the first) does not reach deeper into the bottle than 1 ctm. From this glass tube a rubber tube z runs. Tubes y and z are attached to the limbs of a Y-shaped glass tube Y, while the third lower branch of the Y-shaped tube is connected with the stomach-tube s. The tubes x, a, y, z are provided with compressors. Bottle A is filled with water, bottle B with distilled water or medicinal solution, bottle C is empty. All the compressors are closed in rest. If we open compressor x the water of bottle A runs out, and, on its level, a vacuum is formed and suction through the tube a is exerted. By the opening of compressor a the bottle C is acted upon by aspiration. Let us now open compressor z; the stomach contents will be aspirated into the bottle C and remain there. The more the water is allowed to escape from bottle A through x the more the stomach contents are collected in bottle C. After bottle C is filled it is emptied and again connected or replaced by another. By closing compressor x, a, z, and opening compressor y, the liquid from bottle B flows into the stomach.

Let us now return to the previous subject under consideration. To have our experiment technically correct we must first assure ourselves that the sound—it makes no difference whether only the fenestrum or a greater part of the sound—rests upon the mucous membrane of the lower curvature. This can be easily demonstrated: I let about 100 grammes of water from bot-

tle B run into the stomach, then I close compressor y and open compressors x, a, z. If my sound lies at the bottom of the stomach, the water must be sucked out. If this is not the case I then push the sound downward until the bottom is reached and aspiration of the water takes place. This done, I disconnect the Y-shaped glass tube from tube y and connect the former with a long rubber tube (1 to 1½ yard long) having at the other end a funnel, the neck of which is 1 to 1½ foot



long, L. The funnel L is raised up high and water is poured in, which flows into the stomach as long as the funnel is in an elevated position. This pouring in of water is continued as long as the patient is able to endure it, or according to the physician's judgment, the quantity being here of no importance. If a sufficient quantity of water has been introduced I lower the funnel with a quick motion without turning it. The water-column in the funnel is now at the same height as the water column in the stomach. Next I place the funnel on the anterior wall of the abdomen in such a way that the upper border of the funnel rests upon the sternum, and thus I am enabled to mark with a lead pencil on the skin the water-height in the stomach. Maintaining the funnel in the same position with its compressor closed I open the compressors x, a, z; the water is sucked out of the stomach until but little of the water remains within. Simultaneously if I open compressor l there is a drop in the water-level in the funnel. The height of the water surface in the funnel is now again marked on the abdominal wall. This point, it will be self-understood, is the lower limit of the stomach. To be more accurate, the bottles and funnel can be graduated in order to read down the quantity of water introduced into the stomach and quantity removed. In this way the limit for the normal stomach could also be drawn on the neck of the funnel, which could serve as a standard relatively representing the length of the vertical stomach diameter.

The application of this apparatus avoids one of the main inconveniences in the measurement of the stomach, namely, the artificial lowering of the greater curvature. Whatever the quantity of water introduced, no matter how much the lower wall of the stomach sinks down by pressure, it is always bound to finally return to its natural height as soon as the water is withdrawn, and the line of the lower limit is distinctly marked. Having found the lower point we draw a perpendicular line upward to the cardia. The cardia is situated behind the sternum at the point of junction between the cartilage of the seventh rib and the sternum.

The application of this apparatus is not only of advantage for diagnosis in dilatation of the stomach, but is also useful to determine the mechanical power of the gastric wall. If the elasticity of the muscular layers is not weakened, the water-level on introduction of water into the stomach will rise steadily higher and higher; whereas, in atony of the gastric muscle substance the water-level will to a certain extent sink lower and lower. This enables us then to differentiate a dilatation due to atony from other forms. Whether the dilatation is primary, or the result of constriction of the pylorus, the course of the disease and other symptoms (as swelling at the pyloric region, etc.) will teach us. Ordinarily consecutive dilatation does not occur under the form of atony, for the reason that in consequence of increased exertion the tendency of the gastric muscular layer is to become hypertrophied.

We agree with the view of Dr. Peyer, who expresses himself in his "Treatise on Neurotic Diseases of the Intestines"[1] as follows: "The more exactly and conscientiously one inquires after the causes, the more does the number of pure neuroses shrink, *i.e.*, those diseases whose foundation upon pathologico-anatomical changes cannot be proven." We must also conclude that nervous stomach affections do not occur as often in practice as is generally assumed. If we are finally satisfied, after careful examination, that the existence of anatomical changes in the stomach is out of the question, notwithstanding the presence of symptoms in that direction, we must still not leave out of consideration a series of diseases in distant organs which may be responsible for the suffering. In the first line come the changes in the female generative organs and kidney apparatus, which, it must be admitted, have no direct influence upon the functions of the stomach. This organ, however, may be drawn into coparticipation either by the way of the nerve-tracts or by accumulation of noxious substances in the circulation. In any case the stomach complaints cease when the primary disease is abolished. On a smaller scale the same is true of disturbances of the blood circulation, heart, lungs, liver. The condition of changes in the blood itself is of such a nature that the patient's as well as the physician's attention is called to it before stomach disturbances make their appearance. In a general way, however, a distant organ should never be blamed for nervous phenomena of the stomach unless there is sufficient evidence that that organ is actually responsible for it. I should never designate an intermittent stomach disorder as malaria, so long as I did not find a swollen spleen (plasmodia are hardly found in chronic forms); neither would the good services of quinine convince me of the correctness of the diagnosis; indeed, a facial and trigeminal neuralgia is almost exclusively of intermittent character, and quinine is also in these cases effective, but only those cases can pass as malarial, even when typical attacks do not occur, when there is swelling of the spleen.

Now if all possible diseases which could influence indirectly the gastric functions, or, in other words, if all the symptomatic gastric diseases are excluded, then those diseases come under consideration which draw the activity of the stomach into coparticipation by way of the different nerve-tracts, as in cerebral troubles, diseases of the membranes of the brain, and spinal diseases (crises viscerales) as well as diseases of the peripheral nerves.

In conclusion, I wish to call attention to the fact that the exact chemical and mechanical examination of the stomach and its contents is not only an indispensable means for the diagnosis of the disease, but plays a prominent part in the therapo-diagnosis, serving as a more correct measure of determining the progress of the disease or the cure. When is the patient to be dis-

[1] Wiener Klinik, 1893.

charged from medical treatment? Surely not as soon as the subjective symptoms have disappeared from the scene. The recovery of such a patient cannot be considered as unquestionably settled unless it is corroborated by the examination of the stomach contents, which must prove to be normal, and the mechanism of the stomach, which must be again restored to its normal activity. These conditions can only be objectively determined by means of the sound. Of course symptomatic and consecutive diseases follow their course according to the basis of the fundamental disorder.

94 Rivington Street.

MEDICINAL INCOMPATIBILITY.[1]

By EDWARD C. HILL, M.Sc., M.D.,

Professor of Chemistry, Gross Medical College, Denver, Col.

Chemical substances are said to be incompatible with other substances, if, when they are brought into contact with each other, chemical reaction takes place, with the formation of new and usually insoluble compounds. A knowledge of the ordinary mutually incompatible drugs is of great value to the practising physician, serving to prevent him from prescribing such combinations as are inert, unsightly, unstable, explosive, and poisonous.

In the generally accepted view of the matter, the appellation, chemical incompatibility, has been restricted so as to refer only to chemical decomposition with precipitation of solids or generation of gases. The well-established laws of Berthelet comprise the nucleus of the subject, and are as follows:

1. When two or more substances are brought together in solution, if by any rearrangement of the atoms a product can be formed which is insoluble in the liquid present, that substance will form and separate as a precipitate.

2. When two or more substances are brought together in solution, if a gaseous or volatile body can form, it will do so and escape as a gas or vapor.

An acquaintance with the names of the insoluble compounds of the common metals whose salts are used in medicine, is, for practical purposes, the main thing needed to an understanding of the chemical aspect of prescription writing. Such knowledge, like the multiplication table, or any other arbitrary or empirical facts, must be acquired by distinct mental effort. A few generalizations, however, may aid the memory to grasp and hold the more salient items.

The carbonates, borates, phosphates, arseniates, hydrates, and tannates of most alkaloids and metals, excepting the alkaline (sodium, potassium, lithium, and ammonium), are insoluble in water; hence any aqueous mixture containing the respective elements of which the aforesaid salts are composed would be incompatible. To cite a few common instances in this connection—washing soda (sodium carbonate) "softens hard water" by forming a precipitate of calcium and magnesium carbonates, less soluble in non-carbonated water than are the sulphates of the last-named metals, to which the permanent hardness of aqua communis is principally due. Again, a collyrium containing borax (sodium borate) and zinc sulphate presents a milky, flocculent appearance due to precipitation of borate of zinc. A very common error is the prescribing of a phosphate or phosphoric acid along with iron preparations, with the resulting throwing out of solution of phosphate of iron. The incompatibility of most common metals in relation to arsenic is attested in the case of iron, which is used as a chemical antidote in acute arsenical poisoning, and which may serve to remind you that tests and antidotes generally are incompatible with the substances for which they are employed. Nearly all metallic tannates are insoluble, ferric tannate in aqueous mixture being nothing more nor less than a blue-black ink. Tannin, or tannic acid, is in fact incompatible with nearly everything in the animal and mineral kingdom, with even albumin and gelatin, as our boots testify. Tannic acid constitutes an important part of most vegetable bitters and astringents; calumba, gentian, and quassia being the chief exceptions to its presence. The wide range of its occurrence and of its incompatibility renders the administration of drugs containing tannin a matter of extra precaution. The most noteworthy incompatibility of tannin, is the formation of insoluble tannates with the alkaloidal salts, for all of which it is an efficient chemical antidote. The deleterious effects upon digestion of long-steeped tea or coffee are mainly due to the precipitation of the digestive ferments and of much of the food by the tannic acid contained in these two beverages when badly prepared.

Continuing the enumeration of non-soluble salts, the chlorides, bromides, and iodides of silver, lead, mercurosum, and bismuth are insoluble, as are also the bromides and iodides of nearly all alkaloids. Hence the incompatibility of silver nitrate and sugar of lead with undistilled water, which always contains a variable but ponderable proportion of chloride of sodium and other metals. The fact that calomel (mercurous chloride) may be changed into corrosive sublimate (mercuric chloride) by the coadministration of any acid or salt containing chlorine, should warn us to be careful in this regard. The sulphates of calcium, barium, strontium, lead, and mercurosum are also insoluble in medicinal amounts; hence the objection to the dispensing of Epsom or Glauber's salts in lime-water, and the reason for the antidotal use of these salts in cases of acute lead poisoning. The metallic sulphides are nearly all insoluble and of a black color. The dark appearance of a patient's fæces after exhibition of preparations of iron or bismuth, for instance, is due to reaction with the sulphuretted hydrogen of the intestines, resulting in the formation of the sulphides of these metals.

The second law of Berthelet, relating to incompatibility with evolution of gases, has its most frequent application in the combination of carbonates with stronger acids than carbonic, which, indeed, is about the weakest known. Each of us probably has tried to dissolve potassium acetate and sodium bicarbonate together in a bottle containing water, and has been surprised at the active effervescence which ensued. Similar phenomena are observed on attempting to make a solution of a bicarbonate in boiling water, and on mixing sirup of squills, of which acetic acid is an ingredient, with ammonium carbonate or the compound spirit which contains it. When powerful oxidizing substances, such as nitric and chromic acids, potassium chlorate, and permanganate are brought into contact, forcibly or otherwise, with readily combustible compounds like glycerin, sugar, phosphorus, sulphur and ether—highly explosive gases (or liquids or solids) are liable to be produced, to the alarm of the patient and the discomfiture of the medical man.

A few further rather axiomatic principles remain to be stated: Acids and bases are evidently incompatible, since when brought together they always unite to form salts, which may or may not be insoluble. Stronger acids will displace weaker ones from their combinations in salts: alkaline hydrates and carbonates likewise evict the weaker bases, for example alkaloids, from their saline habitations. Glucosides, such as the glycyrrhizin of licorice root, are decomposed into sugar and other compounds by free acids or alkalies, hence we should never employ aromatic sulphuric acid to dissolve the quinine sulphate in a mixture which also contains licorice for disguising the bitter taste of the salt.

Chemical incompatibility is sometimes intentional on the part of the prescriber, and is brought about usually for the purpose of securing the compound which con-

[1] Read before the Gross Alumni Association, May 2, 1895.

stitutes the precipitate in a fresh, undecomposed state. Common examples of intentional incompatibility are "black wash," "yellow wash," and the pill of silver nitrate and opium.

By way of conclusion it may not be amiss to recall to your recollection the leading points concerning physical and physiological incompatibility. Physical, also known as pharmaceutical, incompatibility, depends upon the differing solubilities of different substances in various solvents. It is an old saying that oil and water will not mix. Water is the best solvent for most inorganic and alkaloidal salts, for gums and sugars, albumins, and gelatin; alcohol dissolves volatile oils, balsams, and resins; glycerin is an excellent excipient for borax, alum, and tannic acid; ether is the solvent for fixed oils and fats. The cardinal rule of pharmaceutical incompatibility is that the solvent power of a menstruum for a substance soluble therein decreases in proportion to the amount of the other menstruum added. For example a very little water added to tincture of camphor, or tincture of guaiac, precipitates a corresponding amount of the camphor or guaiac, making a very unsuitable mixture. Aqueous preparations, for the same reason, should not be combined directly with alcoholic fluid extracts; water added to the fluid extract of cannabis indica, for instance, will cause the resin cannabis to separate to the top of the liquid, with the result that the patient may get poisoned by the first few doses. In accordance with the above rule, also, sweet spirits of nitre, a compound ether, as you know, is physically immissible with the purely alcoholic tincture of guaiac and the aqueous solution mucilage. The medicinal aromatic waters, containing only one minim of volatile oil to the ounce, are rendered turbid by the precipitated oil on attempting to make a saturated solution of any inorganic salt. When it is necessary to combine substances soluble in water with those soluble in alcohol the pharmacist employs, under the physician's direction, acacia, yolk of egg, or some other viscid substance wherewith to emulsify and hold in suspension the oil or resin. Cow's milk is a good natural emulsion, and many medicines insoluble in water and which in a condensed form would irritate the stomach, are administered advantageously dose by dose in the former fluid. This is especially true of strong metallic drugs, nearly all of which need to be converted into albuminates any way prior to absorption. Before leaving the subject of physical incompatibility, allow me to emphasize the distinction between gums considered customarily and the term as applied chemically. In the ordinary botanical sense a gum is any vegetable exudation, and we speak loosely of gum camphor, a stearopten or solidified volatile oil; gum guaiac, a resin or oxidized oil; and of gum arabic, a true chemical gum, soluble in water, insoluble in alcohol, and capable of being converted into glucose by dilute sulphuric acid.

Physiological incompatibility, or better, antagonism, is exemplified by many of our commonest remedies: chloral and strychnine, aconite and digitalis, opium and belladonna. Were the physiological effects of any two certain drugs diametrically opposed throughout, it would of course be utter nonsense to prescribe the two together. But such perfectly adverse properties seldom obtain; we frequently combine bromides with nux vomica, and the hypodermic tablets of morphine and atropine are used in preference to those of morphine alone, since while synergistic in narcotic action, the atropine antagonizes the toxic effect of the morphine upon the heart and respiration.

A well-written original extemporaneous prescription is a work of good judgment based on scientific capability. In writing prescriptions, as in everything else, we should be sure of being right before proceeding. When doubtful as to whether a certain meditated combination is a compatible one or not, it is advisable to prescribe a single drug in the simplest excipient; but on the whole, judicious polypharmacy offers a better prospect of curing quickly, safely, and pleasantly. A very good plan, particularly in the case of readily decomposed alkaloidal salts, such as those of morphine and strychnine, is to prescribe together salts and acids containing the same negative elements (all chlorides, for instance, or all sulphates) thus precluding any possibility of chemical reaction among the ingredients of the preparation. Another common method for solid incompatible drugs is to dispense them in capsular and pilular form.

In one short paper it is manifestly impossible to take more than a bird's-eye view of so wide a subject as the one you have assigned me, but I trust the few remarks I have essayed may be of some little aid in assisting you to steer between the Scylla and Charybdis of prescription writing, namely, routine imitation, and blind, foolhardy ignorance.

A FEW OTOLOGICAL AND RHINOLOGICAL DON'TS; OR, WHAT NOT TO DO IN EAR AND NOSE CONDITIONS.[1]

By N. S. ROBERTS, M.D.,

ASSISTANT SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; SURGEON TO THE NEW YORK THROAT AND NOSE HOSPITAL.

It is not the purpose of this communication to promulgate novelties in fact or theory. Some of the views contained herein may be at variance with the opinions of others, but founded as they are upon a somewhat wide experience in clinical and private practice, and extending over a number of years, I am convinced of their truth and importance, and that they will in the main receive the endorsement of practical workers, although time and space do not permit of much in the way of cases or statistics. Rhinology in particular has made rapid advances, and attracted more and more the attention of practitioners, and most men who aspire to be widely accomplished learn to employ the head-mirror in their practice.

It became early recognized that an important point in the treatment of nasal catarrh was to secure freedom of respiration and drainage, and in the enthusiastic efforts to accomplish this, the work of the cautery, trephine, burr, saw, chisel, snare, and plane, have often been carried to an unwarrantable extreme. In the ear, on the contrary, the sins have mostly been those of omission, so that the surgeon who is led to confess, as to the nose, that he has "done those things he ought not to have done," might say of the ear, with equal truth, that he has "left undone those things that he ought to have done," for that reason my otological don'ts will some of them take a double negative form. I shall not pretend to cover the whole ground, but to touch lightly upon such points as seem most important.

Beginning with the ear, I would say, Don't treat earache with chloroform, laudanum, or camphorated oil; they are inefficient, and may excite local inflammation; it is better to fill the ear with hot water, with or without glycerine, apply a poultice, and if pain persists, apply a leach to the tragus.

Don't advise or permit a patient with profuse otorrhœa to constantly wear cotton in the ear; it causes retention of discharge, and operates against that diligent attention to cleansing and other treatment which would otherwise be given.

Don't use the galvano-cautery in the auditory canal, it is liable to be followed by such consequences as necrosis, ulceration, otitis externa, or stenosis.

Don't blow insoluble powders into the ear, where there is a purulent discharge through a small perforation, it may appear to stop the discharge, but it does so usually by occluding the perforation, and may be followed by worse conditions.

Don't neglect to look for ear complications in all

[1] Read before the New York Medical Union, April 9, 1895.

eruptive fevers, typhoid fever, diphtheria, and low types of pneumonia.

Don't Politzerize through nares in which there is stored up foul catarrhal mucus.

Don't Politzerize with much force in sensitive patients, or those having a thin translucent drum-membrane.

Don't neglect to keep watch of the mastoid prominence in all cases of purulent otitis, and if tenderness, heat, and swelling are found, to take measures to subdue a probable incipient mastoiditis.

Don't overlook, in chronic ear disease, constitutional conditions, such as lithiasis, scorbutus, tuberculosis, and syphilis. This precaution applies likewise to diseases of the nose and throat.

In seeking to enlarge the capacity of the nasal passages, don't forget that in patients of middle age, the tendency is toward atrophy, and don't think it necessary to secure an absolutely normal capacity on both sides, at the expense of an entire turbinated body.

Don't spray the nose with powerful solutions, or only exceptionally with such as give pain.

Don't think that atrophic rhinitis or fetid catarrh can be helped by any medicinal applications, until all inspissated crusts and dried mucus have been removed.

Don't use a douche arranged on the plan of the fountain syringe ; it is pretty certain at some time to cause middle-ear inflammation.

Don't cauterize a turbinated body near a point lying in juxtaposition to the septum, or operate upon the turbinate and septum at one time. The result will probably be an adhesion, and the final state of that person will be worse than the first. In the case named the snare may be used, or cautery be applied to the central interior portion of the growth by the pointed electrode, or by injection of a few drops of dilute carbolic acid or pure iodine tincture.

Don't neglect to give especial attention to the posterior nares and vault of the pharynx ; aside from operative measures, it is in these regions that local treatment will prove most effectual.

Don't make strong applications to the vault of the pharynx, without guarding against the surplus fluid dropping into the larynx, and thus setting up an alarming attack of laryngeal spasm. This can best be avoided by pressing out the excess of fluid from the application, and directing the patient to take a swallow of water immediately after the application is made ; a very good plan also is to wind an extra wad of cotton around the shank of the applicator at about its bend, which will catch and hold any surplus fluid which may be pressed out by the palatal contraction.

Don't under any circumstances cauterize the pharynx above the level of the soft palate. As yet I am not aware that anyone has succeeded in curing adhesions between the palate and wall of the pharynx.

Don't cauterize the septum ; it will result in troublesome ulceration, or not unlikely in proliferation of tissue, producing exostosis or epichondrosis, according as it is either bony or cartilaginous tissue that has been offended.

Don't remove packing from the nose after an operation in less than thirty-six hours, or leave it in longer than sixty ; the former action delays the progress of the case by causing irritation and renewed hemorrhage ; the latter is needless and may result in some septic infection ; don't use any but antiseptic dressings, of which the best is iodoform gauze.

Don't prescribe cocaine preparations for coryza and tell your patient what you are giving ; equally good results may be obtained by the use of hydrastinin nitrate, in two to four per cent. solutions or powders, and with more enduring effect, as well as without reaction.

Don't employ tannin or iron as styptics, thereby producing tardy coagulations, difficult of removal ; if anything short of plugging will suffice, it may be found in antipyrin forty-grain solution, or the pure drug, or in peroxide of hydrogen of about two per cent. volume.

I trust that these hastily written precautions may be of some assistance to those who are anxious to serve their fellow-beings in these special branches of practice.

They have been jotted down at random, as they occurred to mind while writing, and though imperfect, and perchance in some respects open to criticism, they will at least serve the purpose of drawing out the views of men whose opinions I can vouch for as worthy of the greatest consideration.

Progress of Medical Science.

A Simple and Effective Method of Keeping the Obstructed Lachrymal Duct Open.—A subscriber writes us of a "trick" worth knowing, and which he has not seen recorded anywhere in literature on diseases of the eye. The method was devised by Dr. Walter N. Vilas, of El Paso, Texas. It has been tried in a number of cases of lachrymal obstruction and abscess of the lachrymal sac with unfailing success and commends itself for its simplicity, practicability, and radical effectiveness, as well as the important consideration of abridging the treatment of these cases to one sitting. After the necessary preliminary measures of chloroform or cocaine, and the slitting of the canaliculus when demanded, a small-sized probe, armed with a canula, is passed through the canal ; the probe is then withdrawn leaving the canula in place, and through this is passed a strand of silk-worm gut, the lower end being brought out through the nose. The canula is now also removed, and on to the lower end of the silk-worm gut is fastened by pincers a split shot of aluminum (lead will answer), and this is pulled up until its further progress is obstructed, and another shot is now similarly fastened to the gut near its exit from the upper opening to the canal and the superfluous silk-worm gut cut away. The silk-worm gut thus armed with the shot at either end is now left in place until the abscess, fistula, or obstruction disappears and perfect drainage restores the parts to a healthy state. Whether this takes three weeks or six weeks no inconvenience or danger is experienced and the presence of the aluminum shot is not so unsightly as might at first thought appear, and if it were, the result pays for the inconvenience, and then the super-æsthetic or "sound-money" patients might wear gold.

Bright's Disease without Albuminuria.—Marion (*Arch. Gén. de Méd.*, March, 1895), after referring to the recorded cases, relates three cases of unquestionable nephritis occurring in patients aged fifty-eight, nineteen, and fifty-nine years respectively. In the first case there never was albuminuria while the patient was under observation. In the second case, a chlorotic girl was admitted with many of the symptoms of Bright's disease, and yet there was no albuminuria. Two years later she was readmitted, when albumin was present in the urine. In the third case the patient had been under treatment with Bright's disease and albuminuria. Later she was admitted with influenza. The albumin entirely disappeared, but the symptoms of Bright's disease persisted. The author draws attention to the fact that the quantity of albumin present may be of little prognostic importance, and he relates an illustrative case. Albuminuria is a feature of secondary importance in Bright's disease ; it may occur in health, it may exist in large quantities in cases of Bright's disease with few symptoms, and it may be absent in uræmia. As Dieulafoy says, the important thing in renal disease is not so much what passes out in the urine as what remains behind in the body.—*British Medical Journal.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, June 1, 1895.

A NEW PHASE OF MEDICAL CHARITY.

AT a recent anniversary of one of the large and needy hospitals in the millionaire district of this city a speaker filled with enthusiasm for the benefits of the present hospital system is reported to have said that one of its greatest boons was the saving of expense to the rich man. In proof of such an unjust and outrageous claim he bolstered his statement by comparing the items of expense when a patient was treated at an ordinary hotel by his regular medical attendant with those in a well-equipped charity institution supported by the liberal contributions of a Christian organization. Instead of a daily expenditure of $5 for hotel accommodations, $5 for a trained nurse, $5 per visit for the physician, and $5 more for the board of the nurse, not to speak of the cost of the medicines from an expensive pharmacy, the patient who entered the hospital in question needed only to pay for his board and a private room. All other outlays were unnecessary and were included in the one item named. Naturally in this connection we think of the physician, who is the only one whose services are virtually considered of no account. The high price of the room added to the donations of the charitable enable the hospital to make a handsome profit, even including the general expenses for nurses, medicines, instruments, and dressings. The attending physician or surgeon, who might be looked upon as the real personage who makes any hospital what it is, is not only entirely ignored, but a deliberate attempt is made to swindle him and his outside associates in attempts at gaining a legitimate livelihood. It would appear from all this that the evolution of medical charity is distinctly in the direction of eliminating the doctor. Another step in this direction would be for hospital managers to go into the wholesale proprietary medicine business and prescribe remedies on their own account free of cost to the patients. Why should not money be invested as well and as profitably in medical charities and millionaire clinics, as in railroads, wheat, and mining stock? The men who run the hospitals can command all the needful capital on the hypocritical plea of charity to the poor, can obtain medical services free, can build magnificent edifices, endow beds for cast-off servants, beg for church subscriptions, and what now is to hinder them from running the medical charity business entirely in their own interests? They are doing it all the time, though less openly than the distinguished speaker in question has so frankly admitted.

THE INCREASE OF FAVUS.

WHILE tinea favosa must still be classed among the rarer skin diseases the day has passed when we can regard a case in this city as a very unusual occurrence. It is now only the generalized disease, involving the greater portion of the body's surface, which can excite the admiration of the dermatologist. When the American Dermatological Association came into existence in 1877 and began giving us statistics, they could only muster 32 cases for the whole country, and New York contributed but 4 of this number. Ten years later there were 45, of which 8 were credited to this city. In the report of 1889, however, we find New York's cases given as 37 out of a total of 54. In 1892 the figures take a bound to 92 and 145, only to fall again in the last report to 60 charged to our account out of 100 total for the various large cities of the country. While these figures do not pretend to give an absolutely correct census, they serve to show that the disease has gradually increased and that New York to-day has about three-fifths, whereas she formerly had but one-eighth as her share of the cases. It is not the number which interests us, for, after all, it amounts to but one-third of one per cent. of all skin diseases, and compared with Paris, Glasgow, Belfast, Russian, Hungarian, and Eastern cities our number is small. There are, however, features of the disease, as it presents itself to our consideration, which make it of no little importance. And first among these is the fact, which various writers have mentioned in their reports, that almost all our cases are imported. Secondly, communications to the MEDICAL RECORD at various times show that many of these favus children attend school. Now, if we do not keep them out of the country—which is a great mistake—we should surely try to keep them out of the schools and from infecting others.

A third point to which our attention has recently been called by a correspondent is the inadequate treatment these cases receive in most of our dispensaries. The nature of the disease requires for its eradication more time and attention than can be given to it in the large classes, and sending a favus child into hospital too often means infection of other youngsters, and the much-to-be-dreaded institution epidemic.

If these cases cannot be stopped at quarantine there should be some way provided to corral and keep them apart till cured. We are much too young a country to compete with the old world in favus statistics, and there should be a quick return to the good old times when New York City could boast but four cases of favus.

A Proposed Emergency Hospital for Boston.—A Boston woman, whose name is withheld, has offered to contribute $250,000 for the erection of a new emergency hospital in that city as a memorial to her husband. She imposes only one condition, and that is that the public shall contribute $50,000 additional, as a guarantee of their willingness to maintain the institution.

"A DEADLY DISEASE OF OUR TIMES."

In connection with the cock-sure statement of Mr. Howells that the present race was never so healthy and strong as now, it is interesting to read the following paragraph, written by Dr. T. S. Clouston, Superintendent of the Morningside Asylum, Scotland. He says:

"One terrible form of brain disease, with mental symptoms, is certainly increasing. . . . That malady may be described as a break-down of the great centres of mind and motion in the brain; it always goes on from bad to worse till it renders its victim utterly helpless in mind and body, and kills him in a few years. No cure, and scarcely any mitigation of this latter-day curse, has yet been devised. It is a disease of cities, of restless lives, of active brains in their prime; sometimes of dissipation and debauchery, of life at high pressure commonly."

During the past year the asylums of Scotland received 150 new cases; those of England, 1,400; and those of Ireland, 52. The asylum statistics of this country show an even greater number.

In a single asylum of this State, for example, that at Ogdensburg, there were among the 659 admissions 31 cases of general paresis. This would make the proportion of general paralysis over four per cent.

Among seven State asylums, to which 1,942 patients were admitted in 1890, there were 66 cases of general paralysis, or a little over three per cent. If four per cent. be the general ratio for this disease in the State of New York, then the total number of paretics among the 16,000 insane would be about 640. As a matter of fact, the number is much greater, because the proportion of this disease is larger in the New York and Kings County Asylums than in those of the State at large. But even if there were but 4,000 cases of general paresis among the 100,000 insane of this country, it would be an extraordinary evidence of the development of a disease which in the last century was certainly not known, even if it did exist.

LISTER AND NAPOLEON.

Sir Joseph Lister, says *The Practitioner*, has probably been the means of saving as many lives as Napoleon's ambition destroyed, and his work, unlike that of the master of "big battalions," will live after him in silent but ever-active fertility of good. "We should," our contemporary adds, "perhaps, be thankful that Sir Joseph Lister has been honored at all, for men like him have too often in the world's history been ignored or even persecuted. But what, after all, is the recognition he has received from the State compared with what would have been his had he displayed but an infinitesimal portion of the same capacity in soldiering or in politics? Till the mental vision of the public is corrected by a better appreciation of the 'realities' of things, its moral perspective will be all wrong. It is certain, however, that the time will come when the physician will be held in greater honor than the fighting man."

It will be long before the world prefers the silent victories of science to the dramatic deeds of the great war-lords. There is, in fact, nothing in the discovery and application of antisepsis and asepsis that causes the pulse to beat faster and the mind to glow with excitement and enthusiasm. The achievements of Harvey, of Jenner, of Lister are historic and give to these men undying fame, but they do not appeal to the grand passions of men, nor delight their artistic sense. Hence they will always remain a little in the background. As a benefactor of humanity, Lister, and many other men barely known to the world, quite outrank the great Napoleon, but they will never have anything like the present Napoleonic revival. After all, Napoleon was cast in a giant mould; and he is admired for his colossal work and his extraordinary mind, though his work was one of blood and destruction.

THE INTERNATIONAL CONGRESS OF SCIENTISTS.

There has been an International Congress of Scientists at Chicago during the past week. We turn with interest to the records of its proceedings, expecting something very scientific from an assembly which is a "Congress," and which is international and scientistic—for that seems to be the legitimate adjective in the case. It is composed, we learn, of several hundred men and women, embracing Mental Healers, Truth-seekers, Christian Scientists, Scientists of the Divine, Mental, and Spiritual Orders. These harmonious specialists in spirituality hold as the cardinal principle of belief that "the expression of subjective unity is objective harmony."

The sessions were occupied with essays, solos, poems, and "a congregational benediction of health."

The interesting feature of this and similar meetings is that they are called in the name of science. As a matter of fact there is nothing further removed from orderliness of thought than the religio-mysticism of the International Scientists.

News of the Week.

State Care of Insane Bill.—The bill to transfer the care of the insane of New York City to the State failed to receive the Mayor's approval and will not become a law. The sentiment of the medical profession of the city was decidedly against the bill in its present form.

The Craig Colony for Epileptics has had the sum of $125,000 appropriated for its use during the coming year. Governor Morton has appointed the new board of managers, twelve in number. Four members of the old board, including Dr. Peterson, Dr. Jones, Mr. Cuddabuck, and Mrs. Wadsworth, are reappointed. Work at the colony will be begun at once for the reception of patients next fall.

The Use of Antitoxin.—Statistics of diphtheria in Connecticut show that in eighty-seven per cent. of the cases where antitoxin has been used the patients have recovered. Since January 1 there have been found 288 cases of diphtheria in the city of Newark. Of these 90 were treated with antitoxin; 199 not so treated. Of the

90 cases, 23 died; of the 199, 60; the percentage of the former being twenty-five, of the latter, thirty-two. The result of the use of antitoxin was a decrease of seven per cent. of diphtheria cases.

In connection with the foregoing favorable accounts of antitoxin, we publish the following telegram from the American Pediatric Society, the meeting of which was held during the past week at Hot Springs:

"*Resolved*, That in the opinion of the American Pediatric Society the evidence thus far produced regarding the effects of diphtheria antitoxin serum justifies its further and more extensive trial.

"SAMUEL S. ADAMS.
"*Secretary.*"

M. Pasteur was recently offered a decoration by the German government in recognition of his labors in the cause of science and for humanity, but has refused to accept it.

The Cholera has died out at Mecca, if the official reports are to be believed, there having been no cases there since May 23d. In Russia, however, there are the usual number of new cases and deaths. Dr. Proust, of Paris, who was a member of the international sanitary conference, has come out in an interview in the *Éclair*, saying that the refusal of Great Britain to apply the decisions of the conference is absolutely criminal. He says that if Europe is invaded by cholera Great Britain alone will be to blame.

Yellow Fever prevails to a considerable extent on both the Gulf and Pacific coasts of Mexico. It is increasing in Cuba, the newly arrived Spanish troops furnishing abundant fuel for the spread of the disease.

A Monument to the Late Professor Billroth.—A statue of the illustrious Billroth was unveiled in the Hospital Rudolfinerhaus on April 25th. Addresses were delivered by Count Wilozek and Dr. Gersuny, director of the hospital, the latter observing in the course of his remarks that the profession of medicine will never forget the eminent operator, whose name is associated with every advance in surgery.

Fast Time to Attend a Sick Man.—We clip the following from a Colorado daily, concerning the flying trip of our friend, Dr. Powers, who lately left this city to reside in Denver. It would appear that he is already in quite an active practice: "J. S. Troy, one of the principal owners of the C. O. D. mine, was taken suddenly and seriously ill to-day, and word was sent to Denver calling Dr. Charles A. Powers to attend him. A special train was ordered over the Midland and it made the fastest time ever made between Denver and Cripple Creek. In three hours and thirty-seven minutes the engine stopped at Grassy. In twelve minutes more the doctor was with his patient in Cripple Creek."

Society Meetings.—THE MAINE MEDICAL ASSOCIATION will hold its forty-third annual meeting in the Common Council Chamber, City Building, Portland, Me., on Wednesday, Thursday, and Friday, June 5th, 6th, and 7th.—THE CONNECTICUT MEDICAL SOCIETY held its one hundred and third annual meeting at Jewell Hall, Hartford, Conn., on May 22d and 23d. Among notable subjects discussed were those on the reports of typhoid fever and the sero-therapy of diphtheria.—A CONGRESS OF GYNECOLOGY, OBSTETRICS, AND DISEASES OF CHILDREN will be held at Bordeaux, France, on August 12th and four following days. The subjects on the programme are: "Uterine Displacements;" "The Treatment of Puerperal Septicæmia;" "Malformation of the Lower Limb, more especially Luxation of the Hip and Club foot."

The Hospital Graduates' Club gave their tenth anniversary banquet on Thursday evening, May 23d, at the Hotel Hungaria. Dr. Charles H. Knight presided, and Dr. W. K. Simpson acted as toast-master. Responses on call were made by Drs. George B. Fowler, George F. Shrady, Mr. McElroy, late of the *Tribune*, Drs. W. K. Otis, F. W. Jackson, and E. M. Culver.

The Academie de Medecin, of Paris, recently had to adjourn because there were no papers to be read. The fact is commented upon as remarkable and unfortunate. We grant the former, but deny the latter assertion. We know of societies that would serve the cause of science better if they adjourned because there were too many papers to be read. There are too many societies and too many papers written perfunctorily to fill a date.

Object to the Hospital Tax.—There is said to be opposition in the Marine Corps over the monthly forfeiture of twenty cents by officers and men of the corps in behalf of the Naval Hospital Fund. For many years it has been a practice to deduct from the salaries of the Marine Corps people a small fraction, which is applied to the support of naval hospitals. The question has been sent to the Treasury Department for final decision.

Keokuk College of Physicians and Surgeons diplomas have been refused recognition by the Iowa State Board of Medical Examiners.

The California State Medical Society.—There are two thousand (regular) physicians duly licensed and practising medicine in our State. Of these two thousand only four hundred are members of our State Medical Society; of these four hundred only twenty-five were present on the first forenoon of the recent (April) meeting of the Society at Golden Gate Hall in this city. At the afternoon session the members increased to thirty-five, which was about the average attendance, with the exception of the afternoon of the election, when the number increased quite considerably. This showing is nothing short of disgraceful, and plainly indicates that the medical profession of this State or the State Society is at fault.—*Pacific Medical Journal.*

Epilepsy and Marriage.—In the daily court reports of the Cincinnati press there may have been seen one day last week a decision by Probate Judge Ferris, announcing that he would not issue a marriage license where either of the high contracting parties are sufferers from epileptic disease.

To Prevent Influenza.—A daily dose of one grain of sulphide of calcium is said by Dr. W. E. Green, of the Isle of Wight, to prevent influenza.

Reassured.—Patient: "Ah, doctor, I had great fear of being buried alive until——" Doctor: "Until what?" Patient: "Until you took charge of my case."

The Operating Theatre of the Long Island College Hospital is said to be in an unsanitary and septic condition.

New Cure for Gonorrhœa.—Under this title the Paris correspondent of the *Medical Press* gives an abstract of a lecture by Dr. Routier, of the Hôpital Chochin. Routier says: "Where the gonorrhœa is in its acute stage I would advise you not to interfere. Tell the patient to wear a suspensory bandage, to take an alkaline bath every three days, and in about ten days afterward to come back, and then you will cure him. On the other hand, if the case is one that has been of some weeks' standing the treatment can be commenced at once. Your line of conduct will be guided according to the extent of the affection. If the virus has only attacked the anterior portion of the canal large irrigations without forcing the sphincter will be sufficient, but if the whole of the urethra is affected, urethro-vesical irrigations must be made. In every case accompanied by fistula, abscess, or other complication the treatment should be directed to that end before attempting to cure the gonorrhœa. The *modus operandi* of the treatment is easy, but essential to follow in detail. A reservoir *ad hoc* holding about two quarts is filled with the solution of permanganate of potash (1 to 2,000), warm, if possible. An india-rubber tube of about two yards in length, and terminated with a glass nozzle, is attached to the reservoir. The patient urinates immediately before the operation, so as to wash out any pus that may have collected in the canal since the last micturition. The reservoir being placed about five feet above the penis, the glans and meatus are carefully irrigated, and then the cannula is inserted into the meatus, and the liquid flows in until it reaches the sphincter, when it returns and escapes, and so washes out the anterior portion of the urethra. To attain the posterior portion the fingers press the lips of the meatus against the cannula, and the liquid not being able to return forces the sphincter and penetrates into the bladder. As soon as the patient feels the want to urinate the current is turned off, and the man recommended to press on the penis from time to time while rejecting the solution to stop the flow, by which means the liquid penetrates into all the glands, and its action is increased. The operation can be repeated once or twice. If the liquid cannot enter the bladder with a pressure of five feet, the reservoir can be placed a little higher, for the resistance of the sphincter varies. If the patient is nervous a catheter can be passed, and the nozzle fixed to it. One *séance* a day is sufficient. At the end of eight days your patient will be cured, on the condition that he comes every day to be treated. I have thus treated, in the last few weeks, twenty-five cases of gonorrhœa, of which eight were in the acute stage, and all of them were cured in a week. In order to ascertain if the patient is really cured of his gonorrhœa, instil into his canal a few drops of a solution of nitrate of silver (1 to 1,000); a chemical inflammation is provoked, and if any gonococci have remained a drop of pus will be found in the morning."

An International Sero-therapeutic Institute.—That enterprising medical "daily," the *Riforma Medica*, of Naples, has made a start in introducing the interview into medical journalism. In a recent number, says *The Practitioner*, it published an interview between its editor, Professor Rummo, and Professor Ferrannini and Professor Behring. There is nothing of particular interest in it; in fact, the greater part of the interview would seem to have been occupied with mutual compliments. One gathers, however, that Professor Behring, in view of the present uncertainty as to the strength and purity of antitoxic serum prepared in different laboratories and used in different countries, is anxious to see an International Sero-therapeutic Institute established to which all serum manufactured throughout the world should be sent to be tested by an international committee appointed for the purpose. A standard of strength and quality should be decided on, and the committee should withhold its sanction from any serum which failed to come up to the standard. This should apply not only to the diphtheria antitoxin, but to all kinds of serum intended for therapeutic use. In fact, there should be a control of serum of exactly the same kind as exists in all civilized countries for weights and measures; only it must be international. This would eliminate the element of *chauvinisme*, on which Professor Behring lays great stress as a disturbing influence in scientific matters. It is suggested that the Institute be located in Switzerland. But what is the matter with Chicago?

Remarkable Results by Professor Kocher in the Treatment of Goitre.—At the Congress of German Surgeons which met on April 17th in Berlin, Professor Kocher, of Berne, reported that in the last nine hundred cases operated on by him the method of total extirpation was wholly abandoned, and only the partial operation was performed. Since proceeding in this way he has not had any cases of cachexia strumipriva except in one instance, where the remaining part of the gland was found to be atrophied. This case was cured by the internal administration of thyroid gland. Although he was well satisfied with his results, the mortality being only twelve per cent., he hoped that the number of operations would soon be reduced, and that internal medication would be substituted. He made a very remarkable communication, describing the influence of the internal administration of thyroid extract and phosphate of potassium, and showed several photographs of patients where the reduction of the gland after the use of these internal remedies was very obvious. His address was listened to with much interest, and caused a great sensation. Professor Mikulicz said that the internal use of thymus gland was also able to reduce the goitre. Professor von Eiselsberg had not found this to be the fact in his experience.

Thymus Feeding is said by Mikulicz to be of benefit in Basedow's disease.

The Medical Department of the University of Nashville has severed its connection with the Vanderbilt University. It will erect a building of its own. The university itself expects in 1897 to receive $1,500,000 from the Peabody Fund. The prospects of the medical college are therefore very bright.

The Hanoi Hospital has been officially inaugurated at Tonquin. It contains three hundred beds, and is stated to be excellent in all sanitary arrangements.

Reviews and Notices.

The History of the Pennsylvania Hospital, 1751–1895. By Thomas G. Morton, M.D., President of Medical Staff and Senior Surgeon to Pennsylvania Hospital. Assisted by Frank Woodbury, M.D., Hon. Prof. Clin. Med., Medico-Chirurgical College. Royal 8vo, pp. 574. Philadelphia: Times Printing House.

This elaborately illustrated and handsomely printed work gives the interesting and instructive history of the oldest hospital in the country. The fortunate discovery several years ago of many old and original documents bearing on the first establishment of this great charity impressed the managers with the necessity of gathering them in some enduring form, and they invited Dr. T. G. Morton, the senior surgeon, to arrange and present them in proper form. He, with the assistance of Dr. Woodbury, has so well succeeded that, apart from its purely literary merit and judicious editing, the work will take its place among those of history as a model of its kind. The story is one of trials, obstacles, and final triumphs, and illustrates in all its phases the evolution of the hospital system from the smallest and most primitive of helpful efforts to the grandest triumphs of progressive and helpful humanitarianism. Many of the illustrations are works of art, and aid to make the work proportionately attractive. A number of older documents are presented in fac-simile, while the numerous portraits and biographies of former managers and members of the medical staff give it an unique historical value. It is just to say, in recognition of the arduous labors of the compilers, that it is one of the most complete works of its kind to be found anywhere.

Clinical Gynecology, Medical and Surgical, for Students and Practitioners, by Eminent American Teachers. Edited by John M. Keating, M.D., LL.D., and by Henry C. Coe, M.D., M.R.C.S., Professor of Gynecology, New York Polyclinic. Pp. xviii, 994. Philadelphia: J. B. Lippincott Co. 1895.

The aim of this "Clinical Gynecology" is stated to be the presentation to the student and the practitioner of the views of a number of clinical teachers, selected by the editor because they were known to be progressive and free from hobbies, and yet conservative in their teaching and their practice. The death of Dr. Keating threw the burden of preparation of the volume on Dr. Coe, and while credit is due the former for the selection of the men who prepared the articles, to the latter belongs the full meed of praise for judicious pruning and the consequent appearance of a volume which compares more than favorably with others which have been written of late years, and which in many respects excels all others.

While in the opinion of many there may be too many works and too many systems dealing with gynecology, an exception will certainly be made in favor of the present system, for it is written from the stand-point of modern belief, and it bears the evidence of honest purpose in the advancement of all that may tend to the relief of suffering women. Those who are inclined to criticise the fecundity in literature of gynecologists should remember that in no department of medicine have the changes in teaching been more radical and the alterations in method more marked and advantageous. Those of us who were taught but yesterday, so to speak, have forgotten the major part of this teaching; most of the idols of only a few years back have been buried, and in their stead are new idols destined probably to as short an existence. All this may not entirely redound to the good of womankind, but in the life of an unsettled science change must occur until the science reaches the maturity of exactitude. With these thoughts in mind we are prepared to commend highly this system, in the feeling that while all its teaching may not be found exact, the burden of conservatism under which it is prepared will prevent the student from over-enthusiasm as well as from ultra-nihilism.

The work contains forty-nine chapters, with an introduction by the late William Goodell, whose writings and counsel endeared him so much to the medical profession and to the laity. While praise may be accorded to each of the writers in this volume, the space at our command allows of specific reference to only a few of the articles which especially typify the alterations in technique and in teaching.

That all is not surgery in gynecology is evidenced by reading the excellent chapter on Gynecological Therapeutics, prepared by Bache Emmet, of New York. As a rule too little space is devoted to the medical side of gynecology in current treatises, which includes attention to the system in general, instead of jumping to the conclusion that the poor woman must suffer because of the fact that she has been blessed (or cursed) with uterus and appendages. The reader of this chapter will learn that much may be accomplished without resort to the knife and often without touching the sexual organs at all. Matthew D. Mann, of Buffalo, contributes by far the best analysis of lesions of the genital tract with which we are familiar, simplifying in particular the operative technique. Those who are familiar with the writings of W. M. Polk will not be disappointed in the chapter which treats of Inflammation of the Female Genital Organs, that debatable ground in gynecology, and, in fact, that scene of strife even at the present. The conservatism in teaching of this chapter is marked, the writer realizing to the full the danger of dogmatizing on debatable ground. The chapter treating of Inflammatory Lesions of the Pelvic Peritoneum and Connective Tissue we can hardly call up to date, although the writer, Byford, of Chicago, presents the facts from his stand-point after an admirable fashion. The chapter on Uterine Displacements savors somewhat of antiquity, when we recall the fact that to-day the pessary no longer reigns supreme in gynecology, and yet the writer is to be congratulated in that he has been able to divest his present teaching of much which characterized his writings in the past. The chapter contains more than one admission of faulty teaching in the past, and doubtless the next edition of this system will see a still further use of the pruning-knife. Boldt's chapters on Neoplasms of the Vagina and Uterus are classics, and Coe has maintained his high standards of accuracy and conservatism in his treatment of the topic of Neoplasms of the Ovaries, Tubes, and Broad Ligaments. Palmer's chapter on Functional Diseases is well written and teems with sound advice, but the term functional is not well chosen, for if there is one thing more than another which the student needs to have impressed on him it is the fact that hemorrhage and leucorrhœa are not diseases, but the symptoms of disease.

Among the other contributors whose articles are one and all worthy of study we note: Lusk, of New York; Jewett, of Brooklyn; Allen, of Cleveland; Duhring, Montgomery, and Hirst, of Philadelphia; Williams and Robb, of Baltimore, and Baker and Davenport, of Boston.

Both the student and the practitioner will find the system valuable for the purpose of frequent study and reference.

A Silver Medal has been awarded by the French Government to Madame Morel, who has devoted twenty-five years to the sick, having done especially valuable work during two small-pox epidemics. A similar decoration has been conferred on Madame Dallery for services during an epidemic of typhoid at Dey, in Algiers.

Clinical Department.

A CASE OF ACUTE LARYNGITIS.

By CHARLES S. DICKINSON, M.D.,

JOHNSON CREEK, N. Y.

LATE GOVERNMENT PHYSICIAN AND SURGEON TO FORT STEVENSON, N. D.

On the night of February 28, 1895, I was hastily called to see Lee S——, a boy, six years of age. He had been subject to croup more or less, and the doctor before me diagnosed this attack as one of croup, and prescribed for such, but to no avail, and the child constantly grew worse. The clutching at the throat was the most prominent symptom, with inability to breathe, and in these paroxysms the face became livid, breathing stertorous, and eyes bulged out. I found the child in this condition when I arrived. I hastily took in the situation, noticed there was no "brassy cough" of croup present, and on examining the fauces discovered no symptoms of diphtheria, but great hyperæmia of the mucous membrane of the larynx, with œdema of the glottis. The pulse was rapid, the skin hot and dry, and the bowels constipated. After the spasm was over the child would sink back exhausted on the bed; but there was no moisture of the skin. I now noticed a slight cough; the dyspnœa was very marked. I came to the conclusion that the case was one of acute laryngitis, and set about at once to alleviate the distressing symptoms. I concluded to get the constitutional effects of calomel as soon as possible. I started in with a ij. grain dose every hour till bowels were well opened, and at the same time applied hot mustard and flax-seed poultices to the throat, chest, and scapular regions. The feet were soaked in as hot water as could possibly be borne by the patient. The nurse used a cloth wet with ice-cold water to the throat, which acted very happily, and during the spasm an emetic of syrup of ipecac helped somewhat. In less than two hours the symptoms began to subside, the skin became moist, bowels were opened, spasms became less, and there were longer intervals between the spasms. The last spasm was quite severe while it lasted, but when it passed away the child fell into a sound sleep. The patient was left very weak, with considerable hoarseness and some difficulty in swallowing. The patient at this writing is making an uninterrupted recovery. I wish to draw the attention of the profession to one drug in particular, namely, calomel. I emphasize it. I think it is the most valuable drug we possess as an abortifacient to all acute inflammatory processes, especially those of the air-passages.

A CASE OF URTICARIA DUE TO URIC ACID.

By EDGAR J. SPRATLING, M.D.,

MATTEAWAN STATE HOSPITAL, FISHKILL LANDING, N. Y.

The following case is reported on account of its definite cause, and its rarity from such cause.

C. S——, female dement, aged twenty-four, was noticed, on February 12th last, to have urticarial wheals raised thickly over nearly the whole face. Attention was called to it by the nurse at about 11 A.M., the wheals having appeared since the regular nine o'clock visit, at which time the patient was sitting quiet, inattentive, immobile. She is an almost complete dement, not taking any notice of her surroundings, nor answering voluntarily the usual calls of nature; in short, requiring an infant's care.

On reaching the case the wheals were found to be very large and hard, having a peculiar velvety, somewhat oily, feel, and were easily produced in other parts of the body by slight friction, as was done on the neck and shoulders. Inquiries as to the personal care of the patient failed to give anything unusual on which to base a theory for diagnostic purposes. She was immediately placed in bed and about ten ounces of urine drawn off, which was found on examination to have a specific gravity of 1031, to be highly acid, and to contain no albumin nor sugar; the microscope showed many crystals of uric acid (this was within twenty minutes after the urine was drawn). The distilled water with which the bladder was washed out after the withdrawal of the urine had a specific gravity of 1003 and an acid reaction. Here, too, the microscope revealed the uric-acid crystals, showing that they were actually formed in the bladder and were adherent to its walls. At 3 P.M. four ounces of urine were drawn off, having a specific gravity of 1019, acid; the uric-acid crystals were in lessened amount.

The patient's bowels having in the meantime been thoroughly evacuated, she was allowed to remain quiet for the next twenty-four hours; at this time the wheals had disappeared from the face and shoulders, but were nicely grouped, being very large, in many parts of the body, one continuous group extending over the thighs, external genitals, inguinal and gluteal regions. The urine now had a specific gravity 1029, and many uric-acid crystals; the water used to wash out the bladder again gave the crystals, though lessened in number. In not one of the specimens of urine of the many examined were the number of crystals materially increased on standing. A failure was made in trying to show by the microscope the crystals in the blood which was taken at this time; but after having been allowed to stand for twenty-four hours, and with the aid of the usual reagents, they were easily demonstrated.

Since the second day the patient has had her bladder washed out twice each day; and on the third day afterward the blood and urine both failed to give any crystals, the specific gravity of the latter having fallen to normal. The wheals had now disappeared, and no amount of friction would reproduce them. There has been no recurrence of the trouble.

REPORT OF A CASE OF SEPARATION OF THE EPIPHYSIS OF THE GREAT TROCHANTER.

By WILLIAM B. SAVAGE, M.D.,

EAST ISLIP, N. Y.

Recorded cases of separation of the epiphysis of the great trochanter are very few. Mr. Poland reports a case at Guy's Hospital, one was observed by Mr. Aston Key and recorded by Sir A. Cooper, in which the diagnosis was confirmed after death, and one by McCarthy. The following case may be of interest:

Ivy H——, female, aged eight. On February 26, 1895, while playing with her little brother, was jumped on by him while lying on her left side on the floor. Patient said that after the accident she had walked across the floor unaided, and her attention was called to her right hip by "feeling something pricking her" at that point.

Examination showed a portion of bone just protruding through the skin, over the site of the great trochanter of the right side. This fragment was found to be freely movable beneath the skin, and apparently completely detached from the femur, and by moving it a little to one side a depression could be distinctly felt at the trochanteric site. Upon pressing the fragment again in position, crepitus could be easily made out. Flexion and extension could be made with the injured limb without discomfort, while abduction elicited pain.

The wound in the skin made by the edge of the epiphysis was so small that it was deemed best to replace the piece of bone in position. To this end an extension by weight was put on; both to overcome the

eel-like tendencies of the child and to facilitate inspection of the surface wound; fixation of the epiphysis to the femur was made with bands of adhesive plaster and pads; the whole limb was then steadied between heavy sand bags. The surface wound was dressed antiseptically, and was completely healed six days later.

On March 23d, about four weeks after the receipt of the injury, the child was allowed to get up. At this time the epiphysis was completely united to the femur without any deformity.

The above case differs somewhat from that recorded by Sir A. Cooper, inasmuch as the epiphysis in that case was not displaced, being held in position by its fibrous and tendinous covering, while in the case above reported the fragment was freely movable and drawn away from its natural position by the action of the gluteus medius and minimus muscles.

April 3, 1895.

AN ANENCEPHALOUS MONSTER.

By J. EDWARD TOMPKINS, B.A., M.D.,

FREDERICKSBURG, VA.

THERE appeared in the MEDICAL RECORD of April 20th an article on the above subject by Dr. R. H. Phillimore, of Cookshire, P. Q., Canada. The similarity between the case reported by him and one occurring in my own practice just previous to that time, and that I may add my mite to the literature on the subject of anencephalous monsters, lead me to make the following extract from my case-book:

At 10 P.M., April 6th, I was called to attend Mrs. S—— in her fifth confinement. The four preceding labors had been normal. During the present pregnancy she had enjoyed her accustomed health with the exception of severe pain in the region of the heart. This occurred about the fifth month, and lasted two or three days. On palpation there appeared to be a multiplication of small parts, but only one fœtus could be distinctly made out, which occupied the R. O. A. position. Upon examination per vaginam the os was found to be dilated to about the size of a dollar, occiput occupying position named above, and the feet of another child were detected. Labor proceeded slowly. At 8.30 the next morning I ruptured the membranes, and half an hour later my patient was delivered of two girls, about five minutes intervening between the births. The first weighed four and a half pounds, was well formed, but very cyanotic. It died twelve hours later. The second weighed two and a half pounds, and cried lustily at birth. Its body and extremities were well developed, the shoulders broad. The head presents the chief points of interest. The most striking appearances of this were the smallness, about one-half the natural size, and the extreme prominence of the eyes, which bore a strong resemblance to those of a frog. The tongue protruded, and saliva dribbled from the mouth continually. The nose was flat. Above the superciliary ridge there was no prominence, there being a complete absence of the vertical portion of the frontal bone and poor development of the parietals. The space between the two latter bones and that normally covered by the vertical portion of the frontal was occupied by a red, irregular, pulsating mass covered by a thin, serous-like membrane. This extended from the nasal eminence to the occipital protuberance. The child partook of milk and water from a spoon several times, but died thirty hours after birth, much to the relief of the parents.

Professor Leyden has received the order of St. Anne of the first class from Czar Nicholas, in recognition of his services in attendance upon the late Czar Alexander.

Society Reports.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting held at the New York Academy of Medicine, New York, May 28, 29, and 30, 1895.

FIRST DAY, TUESDAY, MAY 28TH.

THE meeting was called to order at 9.30 A.M. by the President.

The Operative Treatment of Malignant Tumors was the subject of DR. FREDERICK S. DENNIS'S opening address. He directed attention particularly to the curability of malignant tumors by operative procedures, and said that, after all, the curability of the disease was, and would always be, to the surgeon, as well as the patient, the grand question—Can we effect a cure of the given case?

The cause of malignant growth was then discussed by the speaker, who first referred to trauma as an exciting cause. In some cases this cause is traceable, and in other cases it is not observed. It, however, is present in a large proportion of cases, not as a primary, but as an exciting cause. Regarding the bacteriological origin of the disease the speaker said he would not venture to enter into discussion in the present state of the subject.

The influence of mechanical injury was illustrated in the paper by a number of cases, among them fracture of bones and other injuries involving bone-tissue or periosteum. Seven such cases were cited as having been observed by the speaker, in all of which there had been injury to bone, and in which malignant growth had developed at the seat of injury soon after. Microscopical examinations had been made in each of these cases to prove the correctness of the diagnosis. Such instances, he thought, were strongly indicative of inflammatory agency in exciting malignant growths. In this connection he mentioned a case of eczema in which cancer developed, and which had come under the author's notice, and another case was referred to, in which epithelioma of the mouth had developed upon wearing a red rubber plate for false teeth. Probably the mercury, one of the ingredients of the plate, was the particular causative irritant present. A case of cancer of the leg, growing at the site of an ulcer, was also mentioned, and also three other cases were referred to in which ulcers, in different situations, had been followed by cancerous growths. The speaker said that, in epithelioma of the mouth in smokers, probably the agent exciting the cancerous development was the nicotine of the tobacco. A clean pipe-stem probably would not excite the growth, but one saturated with nicotine might. Two cases were mentioned as having come under his observation, of cancer excited by eye-glass springs. Necrosed bone from gunshot wounds was another cause which the reader had observed.

In all these conditions mentioned above, and the like, the speaker said, the mechanical injury and irritation must not be regarded as the original cause of the disease, but only an exciting one, in those individuals already predisposed to it by heredity or acquired conditions. Benign growths, such as moles, warts, papillomata, and others, apparently act frequently as exciting agents of malignancy. The questions, then, to be discussed were: 1. Has traumatism or irritation anything to do with the etiology of malignant growths? 2. If so, what is the relation of this cause to the effects? 3. If traumatism or irritation has no share in the etiology of malignant tumors, how can the cases which have been reported in this paper be explained? 4. If this cause be admitted, on the other hand, how then can we explain the development of malignant growths in the absence of traumatic agencies? 5. Would not the theory of traumatic influence imply the purely local

origin of malignant disease? 6. Do not the cases operated on early demonstrate the correctness of the theory, that by removal of the local infection, constitutional affection can be avoided?

Treatment.—The speaker said that he had made a most careful study of his cases for many years, correctly recording every fact of importance and following up each case, when possible, to get at the subsequent history, in order to arrive at reliable conclusions as to the actual value of operative treatment in cancer and other malignant tumors. He said that there was nothing particularly new by way of results for him to present, but he simply would add his experience to that of others. He declared that a radical operation for malignant tumor signifies something more than is implied by the term as ordinarily employed in other fields. The amputation alone of an extremity affected by cancer is not necessarily or probably radical so far as removal of the disease is concerned. The absolutely complete removal of all affected tissue, glandular or other, is implicated in the term radical operation, as applied to the removal of malignant tumors. The surgeon must find out what glands should be removed. Often near-by glands are unaffected, while remote ones are diseased. Operative procedures should not be abandoned as useless in any case because there is local recurrence, but the operation should be repeated an indefinite number of times, and so long as there is local recurrence which is removable by the knife and systemic affection has not occurred. The speaker referred to several cases of his in which, after many recurrences and many operations, the patients had finally recovered.

The speaker then referred to the published experience of several operators of prominence in Europe who have reported no recoveries in sarcoma of glands after their removal by operation. This experience was not in accord with his own, which had given him twelve recoveries out of thirteen cases. He also called attention to the great percentage of deaths which results from malignant tumors, to emphasize the great importance of providing a remedy for the disease.

As to statistics, in cases of epithelioma of the face he had had no mortality. Of 97 amputations of extremities there was but one death, and this due to hæmophalia—practically no mortality. Of 97 amputations of the breast, there were 23 cases of sarcoma and other tumors than cancer, leaving 74 cases of pure cancer. Of these he had subsequent histories of 43 cases; 3 of these have not yet reached the three years' time limit. This leaves 38 cases of cancer in which subsequent histories are in his possession. Of these there have been 17 permanent recoveries—forty-five per cent. Among these 38 cases there were but two local recurrences—about five per cent. These are statistics published by him prior to 1891. Since then the speaker reports 15 cases of pure cancer of the breast with no mortality from the operation itself. There were two deaths from other causes among them. He desired to emphasize the importance of early removal of benign tumors, and most particularly because their presence is liable to excite the development of malignant growth, and because we can never know when the change from benignity to malignancy may begin to develop.

The Radical Cure of Hernia.—This was the subject next discussed, and Dr. John H. Packard, of Philadelphia, Pa., was the first speaker. The speaker had arrived at the conclusion, after careful study of cases and dissections, that the prevalent ideas of the anatomical relations present in inguinal hernia are incorrect. He had arrived at the conclusion that the sac descends without any reference to the cord. The rupture is independent of relations to the cord. In many cases, although the sac may envelop the cord, it is distinct from it and easily separated. The speaker gave demonstrations by drawings of his theory regarding this matter. In most cases the hernia does not come down under the infundibulum fascia, but when it does and it becomes scrotal, we have the infantile form of hernia. Dissections show the sac of the hernia and the sheath of the cord to be distinct and separate, except in the infantile form of hernia. This the speaker had demonstrated by his own dissections, by study of those of others, and by the study of cases on the operating-table.

In the radical cure of hernia it seems, therefore, that we need not interfere at all with the cord. He described his mode of procedure in operating, adapted to his theory of conditions present. In this operation, after a curved incision through the skin, and carried down to the sac, the finger being passed up into the sac, the sac is stitched up and made to form a plug at the ring, and the cord is left untouched. After this, any other operation may be done to supplement it, such as McBurney's.

Dr. McBurney, in further discussion, said that he should confine himself to inguinal hernia. Nothing was more remarkable than the rapid development of the radical operative treatment of hernia during the past eight or nine years.

His opinion differed somewhat from that of Dr. Packard as to the importance of the fascias, etc., at the abdominal ring, in connection with the subject of operation. As McEwen shows, the most important point is the total obliteration of the sac. A plug should not be left, but the sac should be entirely obliterated. The speaker did not believe that surgeons would ever return from that position to the one they had abandoned, that of leaving the sac. The sac having been removed, how shall we prevent recurrence of the hernia? The key of this accomplishment is in removal of the cord and placing it in a new position, together with entire obliteration of the sacs. Closure of the inguinal canal so long as the cord remains in it is, of course, impossible. As to the operation which goes under his name, the speaker remarked that it was devised when the subject was very undeveloped. He does not feel at all satisfied with its results, in comparison with those of other operations more recently devised—that of Dr. Halsted, for instance. In certain conditions of hernia his operation is still advisable, but not in many cases. The greatest obstacle is met in a class of cases in which there is a large, distended canal and in flabby individuals. In absence of this condition his operation will, for the most part, be effective. But the chief point of its weakness is in the shrinkage of cicatricial tissue, especially in the class of cases referred to.

The constant movement and stretching of tissue, especially noticeable in flabby individuals, favor absorption of cicatricial tissue and occurrence of hernia. Dr. Halsted's operation, the speaker said, he believed, meets the requirements best of any operation yet devised. One of the advantages in the operation is the removal of the large veins.

Dr. John E. Owens, of Chicago, said that he had nothing new to offer. He did not think we could expect the same anatomical relations always to be present, as implied by Dr. Packard. On the contrary, a great variety of pathological conditions were found. Each case had its own peculiarities. We ought to go farther than we have and follow the pathological leadings to the end. The speaker was disposed to disagree somewhat with Dr. McBurney regarding the importance of removal of the sac. He preferred to fold it up and sew it in as a plug, and have the cord dealt with according to the circumstances—of varicose veins, etc.

Dr. Halsted's operation was a good one, but not infallible, as we were only too sure to learn by experience. He referred to Dr. Coley's allowing his cases to get up and go about two or three weeks after the operation. His experience did not justify this practice, but showed the necessity of keeping the patient in bed two months, and that a support should be worn for some time after that.

Dr. Halsted, of Baltimore, was then called upon by the President, and related his experience which led to the devising of his operation. The operation is nothing more than sewing up the wound which nature and we, the surgeons, have made. Upon the perfect accomplishment of this depends the permanence of our results. He would caution against the too indiscriminate removal of veins in his operation. This should be done only when they are enlarged, as their removal has been in several cases followed by loss of the testicle. But the chance of this, about one in fifty, should not deter us from the removal of veins if the success of the operation appears to depend upon it. The removal of the sac has not been proved absolutely essential in all cases, but is very important, at least, in most. Three weeks is not too long to keep the patient in bed ; this is probably not long enough. In a patient dying from other cause, twelve days after operation for hernia, the autopsy showed that the wound could be easily torn open. Another like case showed the same thing, after about the same time.

One speaker said that he operated so as to leave the cord in an oblique direction upward.

Dr. Warren said he had made some experiments to determine the resistance of the abdominal adhesions. These showed that it took considerable time for complicated cases to heal. The connective tissue of the canal is of the same general nature, and requires the same time to heal.

Another speaker said that he exacted a promise of his patients to remain six weeks in bed after the operation.

Dr. Van Derveer, of Albany, N. Y., said that as to sutures to be employed, he had been disappointed with catgut ; silkworm sutures had proved more satisfactory.

Dr. Packard, in conclusion, said that notwithstanding adverse criticism, he still believed that his theory was true of a large number of cases and would modify the character of operations in the future.

Result of Treatment of Hypertrophy of the Prostate was the subject of the next paper, which was read by Dr. J. William White, of Philadelphia, Pa.

Causation.—Sinot's theory was referred to, that prostatic hypertrophy is a natural hypertrophy of age, while others teach it to be the result of other causes, such as excessive sexual intercourse, etc. Changes in the male caused by change in testicles, are, the reader said, analogous to change in the female caused by change in the ovaries. The effects of injections of spermatic extract was referred to in this connection. The prostate is in close relation with the testicles in the male, as the ovaries with the womb in the female. The close nervous association, controlling blood-supply, between these organs is evident. Cell-development is regulated by nerve-function, and is a more important matter in this connection than is recognized generally. The testicle secretes spermatic fluid long after spermatozoa ceased to exist in it and after the power of reproduction has ceased to exist. In such cases the removal of the testicle has the same effect upon the hypertrophy of the prostate as in those in whom the reproductive function still exists. The testicles have a twofold function, that of reproduction and that of imparting the quality of masculinity to the individual. Possibly it is the perversion of the latter function, after the former has ceased to be active, which imparts the motive force to cause the hypertrophy of the prostate, a closely associated organ, as shown above. One hundred and eleven cases, the reader said, had been collected by him, of operation by double castration for prostatic hypertrophy, and he related the histories of three of these in detail as examples, to show the cases were genuine ones, and that the conclusions were reliably drawn. One of these was a case which occurred in a New York hospital and was under very reputable surgeons. These cases were extreme and aggravated types, and had been under observation for a considerable time, all by competent surgeons, and had resulted in cures. The relation of these cases seemed to be required in order to overcome criticisms made that the observations had not been of sufficient reliability to warrant the drawing of conclusions. The reader does not regard the operation as any longer experimental. One of the one hundred and eleven cases was a chronic hospital patient, had been regarded as hopeless, but notwithstanding was greatly relieved, if not cured, by the operation. The claim that the results are due to other measures adopted than the operation is not tenable. Such results are not observed from rest in bed, medication, hygiene, etc. The rapid disappearance, often observed, of the hypertrophic tissue after castration is remarkable, but is explainable upon physiological grounds probably. The cure of the accompanying cystitis in these cases comes about as the natural result probably of the removal of prostatic obstructions which have existed, to the flow of urine.

There were twenty deaths from the operation among the one hundred and eleven cases reported. The history of these cases shows that the deaths occurred in complicated conditions in many instances.

The conclusions, the reader said, which seemed inevitable are :

1. The functions of the testicle, like those of the ovaries, are two-fold—the one reproductive, the other for the development and preservation of individual sexual characteristics. Need of exercise of the latter function ceases with the advent of full adult life ; but possibly it does not disappear, and that the hypertrophies in closely allied organs, like the testicle and prostate, result from this misdirected energy.

2. Theoretical objections to the operation of double castration have been fully negatived by clinical experience, which in 87.2 per cent. show that rapid atrophy of the prostate follows the operation ; and that disappearance or great lessening of long-standing cystitis takes place in fifty-two per cent.; more or less disappearance of vesicle dilatation in sixty-six per cent.; amelioration of most of the troublesome symptoms, in eighty-three per cent.; and a return to local conditions, not very far removed from normal, may be expected in considerable number of cases (in 46.4 per cent.).

3. The deaths have been 20 in 111 cases, eighteen per cent.; but of these, 12 may be fairly excluded in obtaining a legitimate estimate of mortality from the operation. This leaves a mortality of seven per cent. It should be noted that in the desperate cases in which death occurred, seventy-five per cent. showed shrinkage of the prostate before death occurred.

4. The operation would seem to offer greater prospects of permanent return of nearly normal conditions than does any other method of treatment. The relative degree of improvement should be taken into consideration in relation to the mortality, in comparing the operation with various forms of prostatotomy and prostatectomy ; so should the absence of any risk of fistula, and also the ease and quickness with which the operation may be performed.

5. The evidence as to unilateral castration is at present contradictory, but there is no doubt that in some cases it is followed by unilateral atrophy of the testicle ; and in two cases, at least, it has resulted in marked improvement of the symptoms.

6. Experiments of the author on dogs show in nearly every case in which the vas deferens was tied or divided on both sides, that without much change in the testicle, there were beginning atrophy of prostate with considerable loss in its weight.

7. Ligation of the vascular constituents of the cord, or of the whole cord, produce atrophy of the prostate, but in the experiments, only after first causing disorganization of the testis.

Time for adjournment having arrived, the President said that the discussion of the paper would be postponed until Wednesday morning.

(To be continued.)

AMERICAN GYNECOLOGICAL SOCIETY.

Twentieth Annual Meeting, held in Baltimore, May 28, 29, and 30, 1895.

MATTHEW D. MANN, M.D., OF BUFFALO, PRESIDENT.

FIRST DAY, TUESDAY, MAY 28TH.

Address of Welcome.—DR. ASHBY read an address of welcome to the members at this meeting.

The Renal Catheter and its Use in Diagnosis and Treatment of Renal Diseases.—DR. HOWARD A. KELLY in this paper described his method of catheterizing the ureters, related five illustrative cases, and gave a summary of his conclusions. A long silk catheter is used, coated with shellac. It was introduced by the aid of the ureteroscope. Precautions were taken against infection. By the aid of the renal catheter he had been able to locate exactly stricture in the ureter; to demonstrate in other cases the permeability of the canal, and thus show that the cause of anuria on one side rested higher; to diagnosticate hydronephrosis and pyelonephritis, and to distinguish between the two; to distinguish between soft malignant disease of the kidney and fluid accumulation in its pelvis; to distinguish the exact nature of the infection in pyelitis. In one case the cause of pain and suppurative discharge was proven to be due to stone by the passage of small stones through the catheter introduced up to the pelvis of the kidney.

During the course of the discussion, DR. KELLY stated that a good light was necessary in introducing the urethral catheter. With proper light, the introduction was much more easily accomplished by sight than simply by touch, and was attended by less danger.

Discussion was participated in by Drs. Etheridge, Mundé, Gordon, Skene, Bache, Emmet, Baldy and Mann.

Further Experience and Observations in Hysterectomy for Fibroids.—DR. S. C. GORDON, of Portland, Me., read a paper which was confirmatory of experience and conclusions regarding the treatment of uterine fibroids treated by hysterectomy, as stated in a paper read before this Society two years ago. His practice was to completely remove the uterus containing the fibroid by abdominal operation whenever the tumor caused sufficient symptoms to drive the patient to the surgeon for relief, and provided it could not be removed easily by enucleation or morcellation through the vagina. He had so operated in about twenty cases the past year with no deaths, in half of which a portion of the cervix was left. As a rule he preferred total extirpation. Catgut suture was employed. Dr. Gordon claimed that no uterus could long remain healthy with a fibroid; septic material was likely to form and infect the tubes and peritoneal cavity; a certain percentage of cases would go on to malignant change. Discussion took place in connection with the next paper.

The Use of Traction and Morcellation in the Removal of Fibroids versus Hysterectomy.—DR. T. ADDIS EMMET read a portion of his paper on this subject. He said the method of treatment by traction and morcellation was one but little known to the profession, notwithstanding that it had been practised by himself for many years. He now brought it forward again, because of a firm belief that, properly practised, it should be the means of greatly reducing the number of cases where total extirpation was resorted to. We were yet in the transition stage, where the tendency was to run to one extreme or the other. Dr. Emmet would no more accept the view that the uterus should be removed from the fact a fibroid existed, than condemn the operation with the dictum that it should never be performed. Abuse in removing the uterus was due to the enterprising spirit of different members of the profession in seeking for what was thought by them to be progress, but, owing to the extreme views held, the result was malpractice. To remove the uterus in consequence of the existence of a fibrous growth, from which the woman may have suffered little, was not, in his judgment, justifiable. To extirpate the uterus before thoroughly exploring the uterine canal was equally reprehensible. Frequently a secondary growth projecting within the canal was the immediate cause of the loss of blood. The most important point of all, after locating a uterine tumor, was to determine the rapidity of its growth. The tendency to loss of blood could be excluded as an urgent symptom for removal of the uterus, for by proper methods it could be held in check for an indefinite period.

We could grant that hysterectomy had come to be a reasonably safe operation, but the testimony of those who saw the women afterward was that a large proportion of them remained invalids.

Sometimes a cause for their symptoms would be found in sagging of the roof of the pelvis or of the bladder, or of the whole vagina. But in a number of cases no cause for the continuance of the symptoms after removal of the uterus could be found. Dr. Emmet thought these sufficient reasons why hysterectomy should not be done for fibroid unless it were absolutely necessary, and he would add, as a result of personal observation and experience, only to save life.

Taking this view of the case, it was well to bring forward again the method which he had practised many years, since before 1863, of getting rid of uterine fibroids in a manner want of knowledge of which was leading many to frequently sacrifice the entire organ.

Dr. Sims early in his professsional career had forcibly separated a fibroid with a stout steel instrument, and Dr. Thomas had introduced the serrated scoop, but by such means more or less damage was done surrounding uterine tissues, and a cavity was left with a roughened surface which sloughed more or less before the space could become obliterated.

Dr. Emmet said his own procedure was entirely different, consisting in firmly seizing the growth with a large tenaculum or double hook, and by traction exciting sufficient uterine contraction to displace the mass, and by such contraction also closing up the space which the tumor had occupied. Tumors with a broad base and of large size had been successfully enucleated.

Dr. Emmet believed nearly all of these growths had their commencement near the uterine canal, where they would be best nourished, and that the natural tendency was to progress forward and finally project into the uterine canal, and where several were present, removal of the inner ones would be followed by tendency of those more deeply situated to also enter the canal. He believed their origin would be found in perverted nutrition. They occurred less frequently in women who bore children, and after child-birth were apt to disappear.

Ligation of the Pedicle with Catgut.—DR. ARCHIBALD MCLAREN, of St. Paul, in a paper with this title, advocated the use of catgut in intra-abdominal work. Previously he had been opposed to catgut on account of inability to render it sterile, but this objection had been overcome by a physician in St. Paul, who resorted to dry heat at a high temperature, 290° F. The catgut was wrapped in paper and this was placed in the sterilizing tube, and the temperature was raised to the degree named. Prepared in this manner the catgut was not rendered brittle—an objection which was said to apply to dry heat as employed in sterilizing this agent.

DR. A. P. DUDLEY spoke in praise of catgut, while DR. W. M. POLK had found cases do badly under it when treated in other respects exactly like some which had done well under silk ligature. He could not account for the difference in result except on the basis of different ligature material, although he must admit that some of the same catgut was found on bacteriological test to be entirely sterile.

DR. MANN, thought, in view of Dr. Polk's last remark, that his experience was not against catgut but against some unknown agency productive of a bad result.

American Medical Association.

Forty-sixth Annual Meeting, held in Baltimore, May 7, 8, 9, and 10, 1895.

SECTION ON SURGERY.

Second Day, Wednesday, May 8th.

(Continued from page 598.)

Movable Kidney.—This paper was read by Dr. Homer Gage, of Worcester, Mass. He operated on a woman for movable kidney on the right side, and the patient afterward developed a movable kidney on the opposite side. Just before the first operation she felt something give way on the left side while lifting a stove.

Operation.—The kidney was replaced and held in position by three sutures of silk. The woman remained in bed two weeks. Two years after there was no recurrence.

In his second case the speaker used six carbolized sutures. The patient remained free from pain for four months, when the pain returned and shortly afterward the lump reappeared, necessitating a second operation. Dr. Gage split the capsule on the outer border of the kidney and passed five sutures through the fascia. However, the pain again returned, and in the following December the patient entered the hospital for removal of the offending kidney. Upon exposing the kidney firm adhesions were found, and its apparent mobility was due to the relaxed, flabby condition of the tissues. She has remained perfectly well since the removal of the kidney.

The first case was interesting in the entire absence of all but local symptoms. Where other symptoms exist, so much greater will be the chances of failure of the operation, and this was the trouble with the second case, where the operator avoided passing the sutures into the kidney substance itself.

The literature on movable kidney says little or nothing about associated symptoms, such as neurasthenia, hysteria, etc., and where these symptoms are present a nephrectomy may have to be resorted to in the end.

Dr. Wyman, of Detroit, thought the failure of the operation for fixation of the kidney is due to extreme laxity of the peritoneum, and when this is carefully drawn and stitched to the wound no relapse will occur. He claimed that the peritoneum formed a normal support to the kidney, and unless the relaxation is corrected there is risk of a recurrence of the movable kidney.

Dr. Weeks, of Maine, said the sutures should be of silk and should be passed through the substance of the kidney, including the capsule, then through the muscular fascia and be fastened to the posterior part of the incision.

The Radical Cure of Hydrocele.—This paper was read by Dr. D. C. Hawley, of Burlington, Vt. The only known method of absolute cure of hydrocele is the complete obliteration of the tunica vaginalis. Treatment by injection fails sometimes because it is improperly done. Again where the tunica is so thickened that it will not collapse.

Injection by Iodine.—This is painful and causes swelling, confining patients to bed from three to five days, and three to four weeks before recovery. Carbolic acid is less painful, but requires the same length of time.

Incision and Irrigation.—During the past three years the author makes an incision about two inches long over the anterior surface of the tumor; the fluid is allowed to escape; the sac is irrigated and the edges stitched to the skin with black-silk sutures. The interior of the sac is irritated by being rubbed with the finger-tips; the sac is then packed with iodoform gauze and the patient kept in bed. In twenty-four hours the gauze is removed. Strips of adhesive plaster and a light dressing of gauze with adhesive strips around the scrotum is all that is now necessary to secure equal compression, and the suture should be removed in four or five days. Should a sinus be found it should be treated on general principles. Two or three dressings are all that in necessary, and in from six to twelve days the wound is entirely healed. The patient should be kept in bed during the first three or four days, and the scrotum suspended when he gets up. In all his cases treated this way he has had a radical cure. Its advantages over the injection treatment are: quicker results, less pain, and almost absolute success in all instances. This method is not open to the objection of using anæsthetics, as it can be done with cocaine.

Dr. Maclean, of Detroit, said he had seen many different operations for hydrocele, but in his experience the injection of iodine has been as good as any plan brought forward. In every one of his numerous cases he had tapped and injected strong iodine, and in some cases had used Churchill's. The patient is made to stand up, and a good-sized trocar is plunged into the sac, every drop of fluid pressed out, and two drachms of strong iodine injected. The scrotum shaken violently ending the operation. He does not put his patients to bed nor keep them in the hospital, but allows them to go about their business, and he has never failed, except in one case, which was an enormous double hydrocele with complications.

Dr. Maclean's views were indorsed by Drs. Gaston, of Atlanta; Vance, of Kentucky; and Rodman, of Kentucky.

In closing the discussion, Dr. Hawley stated that statistics gave about twenty per cent. of failures in the injection method. In his open method, should there be any disease of the testicle, it would be disclosed.

What Advance has been Made in the Surgical Treatment of Hernia? was the title of a paper read by Dr. W. B. De Garmo, of New York. After passing upon all the well-known methods which came into existence since 1876, he took Bassini's as the one which gives the best results. In this method sutures that are not quickly absorbed should be used, and while McBurney uses silk in his operations, we now use kangaroo tendon. The canal being cleared of all foreign substances, repair begins at the internal ring, and the canal is thus completely obliterated. In operating, opening the canal its entire length is one of the most important things done lately. All fat should be removed, as it acted as a wedge and could be the cause of reopening the canal, and the sooner we recognize the sac as a foreign body, the better will be the results obtained.

Dr. Weeks wished to know whether all cases were to be operated upon for radical cure. He thought all cases which could be controlled by a properly fitting truss should not be operated upon.

Appendicitis.—Dr. John B. Deaver, of Philadelphia, Pa., read a paper with this title. There are many sceptics as to the course of this disease and its radical cure. The diagnosis is easily established. Upon palpation you find a localized point of tenderness. This point of tenderness is of great value. Excruciating tenderness indicates pus. Temperature is not reliable, but a sudden fall often indicates a perforation. Regarding the point of tenderness he had seen cases where it was referred to the left side. Foreign bodies are often retained in the appendix without causing any trouble until a cold brings on a catarrhal inflammation and the foreign substance then causes suppuration. The prognosis depends largely upon whether the operation has been done early in the disease. If the general peritoneal cavity has been invaded, the prognosis is so much the worse. With perforation into the bowel, recovery is the rule; perforation into the bladder is very fatal.

Treatment.—All cases of appendicitis should be operated upon as soon as the diagnosis is made, for there is no possible way of foretelling whether you shall have perforation, gangrene, or pus, or that it will

be a simple catarrhal inflammation. Regarding the danger of operation, one hundred operations without a single death requires no comment. Early operation can be regarded as more of a conservative treatment than a radical one, as one attack is almost sure to be followed by subsequent attacks. Early operation is a comparatively easy procedure, but after pus has been formed the operation demands the best of judgment and skill.

In the operation one should avoid the median incision, because it necessitates a large incision, and the peritoneal cavity cannot be so well protected from infection. Drain the abscess before removing it. Unless you do remove the appendix the operation has not been a curative one. The McBurney operation is the best for chronic cases and prevents hernia.

Dr. J. McFadden Gaston, of Atlanta, said early diagnosis and treatment were essential, but it was not always so easy to determine you had a case of appendicitis. He had a case in which all symptoms were absent while pus was present in abundance.

Dr. McGonigal, of California, said in all early operations his patients recovered. Cases not operated on until four or five days had elapsed, died.

Dr. Quimby, of New Jersey, thought there was a serious mistake in treating every case as a surgical case. In small places where expert surgeons could not be obtained what should be done? He treated this disease as he would peritonitis. We want early treatment and should not resort to the knife and abandon all medical treatment.

Dr. Wyman, of Michigan, said his experience was limited to cases where suppuration already existed, the delayed diagnosis being due to the powerful contraction of the abdominal muscles. As to the cause of the disease, he believed there was a geographical distribution of it, as in malaria, and foreign bodies were merely coincidents.

Dr. Murphy, of Chicago, asked how a diagnosis can best be made? Within twelve hours after the first attack. The varieties of infection governs the symptoms. A blistered condition of the peritoneum, as though parboiled, was far more fatal than the mere presence of pus.

Dr. Marcy, of Boston, indorsed Dr. Murphy's opinion.

Dr. Hawley thought rigidity of the muscles on the right side of the abdomen was evidence enough for operation in every case.

Dr. Herring, of Cleveland, did not think we should be in too much of a hurry to operate.

Dr. Willard believed in early diagnosis and lateral incision.

Dr. Ransohoff, of Cincinnati, thought in cases of circumscribed abscesses the removal of the appendix was not necessary for a radical cure. Drainage appeared to be sufficient.

Dr. Deaver, in closing the discussion, said fully fifty per cent. of his cases, where the appendix had not been removed, had a recurrence of the trouble.

Radical Interference in the Diseases of the Chest was the subject of a paper by J. McFadden Gaston, of Atlanta, Ga., in which he made plea for early operative measures, especially in emphyema.

In the discussion which followed this paper Dr. Smith, of California, claimed to have made experiments upon the rabbit, and by packing the chest with gauze he could stop the hemorrhage and the rabbit recovered. If this can be done with an animal of so low vitality how much better it might be done with man. He believed as much could be done with the pleura as with the peritoneum.

The paper was discussed by others, and the concensus of opinion was that in empyema the best results were obtained from early diagnosis; resection of as many and as large a part of rib as necessary and drainage.

The Treatment of Malignant Tumors by the Toxins of the Streptococcus of Erysipelas was the title of a paper by Dr. Nicholas Senn, of Chicago, Ill. In all of his cases the treatment proved a failure. The effects produced by actual attacks of erysipelas and those produced by injections must differ, because in one instance by limiting it to the superficial lymphatics it must in certain cases result in an obliterance of those pathways. In certain exceptional cases, by obstructing these pathways you might limit the extension of, or completely cure, the disease. In many cases cures were claimed, but the diagnosis had not been corroborated by clinical or microscopical examinations.

The toxins he used were derived from three different sources. He cited nine cases in which he had used from twenty-five to seventy-five injections of from three to fifteen minims at a dose. He failed to obtain a cure in any instance, and in some of the cases the injections aggravated the local and general condition of the patient. The treatment was resorted to only in cases which could not be operated upon, but in no single case were there the slightest beneficial effects produced. However, as nothing else could be done for this class of cases he proposed continuing his experiments with it, but he believed in a year or two this remedy must be relegated to the past.

Dr. Coley, of New York, was invited by the chairman to open the discussion. During the past four years he had treated with the toxins 84 cases of malignant diseases; 43 of these were sarcoma, and 27 carcinoma. His results were 11 cases of sarcoma and 2 cases of carcinoma cured. Since the reading of his last paper he had two additional cures in sarcoma. With 11 successful cases he did not think the remedy stood in much danger of being relegated to the past.

The questions to be answered are: 1. Have toxins any curative effect? 2. Is the cure temporary or permanent? 3. What form of tumors are susceptible to it?

Eleven successful cases answers the first question. As to permanency, three of his cases have gone two years with absolutely no return of the disease. Third question: until the present time I advocated the treatment of nothing but sarcomas. Different forms of sarcoma yield differently. In some cases he had no success whatever.

Dr. Reginald Sayre, of New York, said, while he had no personal experience with it, he had seen some of Dr. Coley's cases before treatment and saw them one year afterward, and they showed no evidence of a return of the disease.

Dr. Fenger, of Chicago, had used it in twelve cases with no benefit.

Dr. Wyeth, of New York, eleven years ago used injections of arsenic around a tumor. It caused great pain and excited wide-spread suppuration, resulting in the man's recovery. He thought this might reconcile the different reports. He had used Dr. Coley's toxins in a case of epithelioma with no result. He thought the good results might be due in great part to the inflammatory action of the injection, which destroyed the rank cells of the growth.

Dr. Herring cited a case where he removed a growth from the abdomen. This growth reached down to the knee. After the operation, erysipelas set in, but it appeared to have no effect except that after the attack the growth appeared to go on more rapidly. This was repeated several times, and the only result was an aggravation of the disease.

Dr. Keen, of Pennsylvania, said he believed the statements made by Dr. Coley were true. However, he had not much faith in the treatment, but used it for two reasons. One, he was not prepared to condemn it; the other, when he met with such cases he would use anything that held out any hope. He proposed to try it further until convinced of its hopelessness. He obtained his toxins from Dr. Coley himself. He used it in cases of sarcoma and carcinoma, but in every instance was disappointed, excepting possibly one. This was a

case of a large angio-sarcoma of the brain. This tumor was too large to be removed entire. At first he removed a portion and subsequently still more, and afterward injected toxins. Two months after ceasing the injections he saw no shrinkage whatever. Some time afterward, when he saw his patient again, the wound had healed over and a great shrinkage had occurred. Whether it will prove a cure he does not know, nor could he say whether it was due to the toxin or not. He had seen cases of abdominal tumors pronounced as sarcoma disappear of themselves.

Replying to Dr. Wyeth's question Dr. Coley thought the action was not entirely a local inflammatory action, for in several of the cases the tumor disappeared without any breaking down whatever, simply absorbed.

Tumor of the Naso-pharynx and Neighboring Parts.—Dr. John A. Wyeth, of New York, read a paper entitled: "An Original Osteoplastic Operation for the Removal of Large Vascular Tumors Growing in the Vault of the Naso-pharynx, Antrum of Highmore, Spheno-maxillary, and Pterygo-maxillary Fissures." He first inserted a cannula into the median cephalic vein and had a quantity of salt solution ready for immediate use. The incision was made along the temporal arch, down parallel with the nose to the level of the ala-nasi, and then brought outward and upward, making an oblique incision. The tissues were dissected loose and carried over, exposing the bone. He then with a key-hole saw separated the frontal bone from the malar bone. The hemorrhage was terrific. At this point he injected a pint of the salt solution. After the removal of the malar bone by depressing the zygomatic bone he had full access to the cavity and the tumors were removed. The various structures were replaced without any bone sutures, everything healed over nicely, and the patient has excellent motion of the eye. The operation lasted but an hour and a half, and about five pints of salt solution were injected in all.

Tumors of the Mammary Gland was the title of a paper read by Dr. W. L. Rodman, of Louisville, Ky., in which he advocated the early and complete removal of the entire mamma, together with the muscles and all surrounding tissues.

Is Total Extirpation of the Rectum Ever Justified? was the title of a paper read by Dr. J. M. Matthews, of Louisville, Ky. This operation has been strongly endorsed by many, but some operations have only to recommend them being done more to test the efficacy and methods of others. There is also a rage in some surgical work, but he is the best surgeon who studies his subject from all standpoints and much responsibility rests upon his decision. Many do not stop to consider whether the new method is as good as the old or not.

Is it justifiable to extirpate? First, is the patient ever cured by the operation? Is he benefited or relieved by the operation? How difficult it is to decide whether we have systemic infection, especially in cases of malignant rectal disease. By the time the growth in the rectum has assumed sufficient size to call attention to it the surrounding tissues are already affected. It is one of the bloodiest operations attempted. He said that one could not cut wide of the growth without invading vital parts, and if all the surrounding tissues could not be removed, why should the operation be performed?

Colotomy and Extirpation in Cases of Cancer of the Rectum.—This paper was read by Dr. L. H. Adler, of Philadelphia, Pa. These are two recognized operations, but the writer never saw a single patient who was benefited by the operation of extirpation. Colotomy retards the growth of the cancerous tumor. It substitutes a painless death for a painful one. It prevents intestinal obstruction, enables the patient to sleep, eat, and be comfortable while he lives, and is a much less dangerous operation than extirpation.

The foregoing three papers were discussed together. Dr. Keen, of Philadelphia, agreed with Dr. Rodman in removing the entire mamma, muscles, and all surrounding tissues likely to be involved. He believed the incision should be beneath the clavicle, along the border of the sterno-mastoid muscle, and every gland removed. This would not increase the mortality of the operation. He knew that English operators claim a high mortality in this, but not so in America. Four hundred and eighty-nine English operations gave a mortality of forty-six. Four hundred and sixty-four American operations gave but four deaths. He believed in extirpation of the rectum. Its mortality has been small and the relief immense. Two years ago he removed the entire rectum in two cases, but in both cases preceded it with a colotomy. He removed the coccyx and a large part of the sacrum, and both patients are well to-day. In another case the rectum, uterus, ovaries, tubes, and all the posterior wall of the vagina were removed, and the woman is perfectly comfortable.

Dr. Fenger, of Chicago, thought that while the operation was an extensive one the patient must take his chances, and by doing such operations we might be able to save some.

Dr. Jacobson said that the operator who claimed rectal extirpation the bloodiest operation did not know the methods of to-day. He knew of no operation for malignant tumor less bloody. He lost no case in this operation where the surrounding tissues were not infiltrated, and the rectum should be excised in every case.

The papers were further discussed by Drs. Davis, Tiffany, Marcy, and others, and while opinion was equally divided as to the advisability of the operation, all agreed that it should only be done early in the disease.

In closing the discussion, Dr. Matthews called attention to the fact that all of his opponents agreed with him in the main. Total extirpation in inoperable cases were the ones he referred to, and it was one of the bloodiest of operations. Are you justified in doing this operation when all the speakers admit that the cases never come to you until the tissues are invaded? Dr. Keen's report is of only two years. After colotomy cases live six years. Can extirpation show as good results? All these gentlemen say they preceded extirpation with colotomy, and since colotomy relieved them, what was the object of extirpation?

Dr. Rodman said that Dr. Keen's statistics for breast operations went back to 1870, which accounted for the high mortality, but he did not think in Germany during the past five years the mortality was higher than here. The English have a high mortality because they do not keep up with the times.

Electrolysis in the Treatment of Sacculated Aneurism.—Dr. D. D. Stewart, of Philadelphia, reported a case of this sort. Gold wire of a sufficient calibre to form spirals was passed into the centre of the aneurismal cavity. Ten feet of wire were passed into the sac. The current was passed without interruption for seventy-five minutes. Before the expiration of half an hour the blood had congealed sufficiently to enable the needle to stand up without support. The operation caused no pain. Three weeks afterward, the upper part of the sac not being entirely occluded, we repeated the operation, but only two and a half inches of wire could be passed at this time. A perfect cure resulted.

SECTION IN MEDICINE.

Third Day, Thursday, May 9th.

The Complications of Malaria was the title of a paper read by Dr. J. M. Anders, of Philadelphia. He had collated the statistics of 2,122 cases. In 1,780 of these, all occurring in the hospitals of his own city during the past twenty years, statistics were sufficiently full and accurate to authorize deductions therefrom. The cases could be classified as follows: Intermittent, 1,434; re-

mittent, 75 ; malarial cachexia, 27 ; chronic and irregular forms, 22 ; unclassified, 222. Of all this number 189 presented distinct complications, viz. : Heart disease, 21 ; enteritis, 21 ; neuralgia, 18 (11 of which were supra-orbital) ; albuminuria, 14 ; pleurisy, 13 ; rheumatism, 13 ; phthisis, 12 ; typhoid fever, 8 ; œdema, 7 ; pneumonia, 6 ; jaundice, 5 ; hepatitis, 5 ; besides some 30 other maladies occurring from one to four times each. He believed that some conditions commonly called complications were in reality symptomatic of the malarial state. In certain chronic conditions (heart troubles, tuberculosis, and nephritis) there might be shown a pre-existing predisposition to malaria, and he was of the opinion that malaria does promote phthisis.

Pleurisy may arise in the course of paludal attacks, but it is probably distinctly secondary. There was some doubt as to the connection of pneumonia with the condition. There was undoubtedly a periodicity of pulmonary symptoms coincident with the malarial crises. Only one pneumonia case in the foregoing list proved fatal, and all occurred in connection with the intermittent type. Of the 6 cases 5 were lobar and 1 catarrhal or lobular. This complication was undoubtedly more common in southern than in northern latitudes.

As to typhoid fever, both poisons could undoubtedly exist at the same time in a given individual, but this is rare. As to the so-called hybrid typho-malaria, he believed it to be more common in the South, and yet he believed that if the blood was examined many of these cases would be found to be pure typhoid. Periodic febrile cases, etc., do occur in typhoid, and the intermittent type of this disease is of a favorable nature.

In discussing the paper, Dr. Rochester inquired if the pleurisies and pneumonias had occurred more frequently on the left side. He thought that if this was the case it might have some relation to the enlarged spleen. He believed that the typhoid temperature often intermits without any malaria.

Dr. Hollister had seen much malaria in the first year or two of his practice. The cases were characterized by rapid cell disintegration, yet did well during the warmer weather on anodynes and quinine, but upon the advent of cold weather they did much worse, and the disease seemed to assume an epidemic character with arachnoid congestion and cerebro-spinal meningitic symptoms. During the next year in the same locality, the poison seemed to expend itself on the pulmonary tract, first as catarrh, and second as serous transudations and infiltrations into the lungs, and many of them were fatal. He believed that the antecedent blood-cell disintegration offered a very fertile medium for the development of Koch's bacilli.

Dr. Anders, in closing the discussion, stated that no observations had been made as to the side involved in pulmonary complications. Most of the pleurisies had been plastic rather than of a sero-fibrinous nature.

The Relative Condition of the Two Ventricles with Reference to the Administration of Digitalis.—Dr. Robert H. Babcock, of Chicago, presented a communication with this title. According to the text-books, the indications given for the use of digitalis in cardiac disease were a weak, rapid, and possibly irregular heart, a low pulse tension, possibly a mitral murmur, a dilated right ventricle, and dropsy. In dilated heart there was a relative arterial anæmia and a relative venous and capillary engorgement. The clinical history of a case of heart disease was given, in which there apparently existed every indication for digitalis, but the drug did harm. The case finally improved on nitro-glycerine and strychnia nitrate. We must distinguish between the actions of foxglove on the two ventricles. The coronary arteries are probably the regulating mechanism under these circumstances. Digitalis is probably useless in dilatation of the right ventricle, and is also probably indicated in extreme cardiac dilatation. We can give the heart a chance by the preliminary abstraction of from eight to ten ounces of blood, or purgatives may answer.

Cardiac Instability Due to Acid Auto-intoxication.—Dr. W. T. English, of Pittsburg, Pa., read the paper. He said that a study of chemical processes in the body explains many of the conditions which we call diathetic. Many abnormal heart phenomena are due to acid accumulation, and acid excretion is contemporaneous with cardiac and vascular irritability. The heart grows weary from disturbance in the nutritive supply to the myocardium. Dilation ensues, with inefficient valvular closure from peripheral tension. Dyspepsia offers a good illustration of the effects of acid excess on the heart. By the agency of the blood the endocardial ganglia and the endocardium itself first became affected, and later the myocardial ganglia through the irritation of the coronary arteries. First of all, we had a sort of cardiac exhilaration, then a shortened systole, and, finally, a lessening of ventricular force and a coming to rest in a state of diastole. Reduced alkalinity of the blood also led to capillary spasm. Similar results followed the exhibition of acid remedies. The pulse tension is increased. The excess of acid may be stored up in the liver, but this organ has an eliminative power, as has also the bowel. Not so, however, with the heart, as it cannot eliminate, and consequently bears the brunt of the strain. Many people live on the acid line, so to speak. Ordinarily they do well ; but increase the acid by drugs or food, and they suffer. The acidity of the body is normally greater during sleep, and there is a diurnal acid tide within limits of health gradually rising toward the late hours of the afternoon. The fatalities in heart diseases and cardiac anguish commonly occur at those hours when the normal acid tide is at its height.

Therapeutics of the Senile Heart.—Dr. A. F. Pattee, of Boston, read a paper with this title. He claimed that in old age the heart returned relatively toward the cardiac condition in childhood. In infancy the vessels are thin and yielding, while in senility they are rigid and stiffened. Finally, the striated muscle of the heart ceases to respond to the demands made upon it, or dies from malnutrition, and death ensues.

In treatment reference must be had to diet, rest, and drugs, and the writer then gave in great detail the various dietetic regulations and drug combinations he was accustomed to employ in his cases. He would avoid stimulants, and would insist upon the use of beef recently killed and not kept in cold storage. Dinner should invariably be taken in the middle of the day, water kept down to a minimum in œdema, and longer intervals should elapse between meals. Cardiac disease sometimes increased the appetite. All condiments should be given up, and vegetables largely, except baked potatoes with cream. Tobacco was prohibited, and also tea and coffee, though the latter might be replaced by certain aromatic infusions. The clothing should be of silk or wool. Warm baths alone should be taken, and hot-air baths with great caution. As to drugs, the writer named over various combinations—including many not usually employed at the present day—and gave the prescriptions in full. Where iodides were indicated, he preferred, as less irritating to the stomach, the modern combinations with rubidium and strontium, rather than the older ones with potassium and sodium.

In the discussion on all the foregoing papers Dr. Rochester took issue with Dr. Babcock as to the indications for digitalis. He believed that an excess of ventricular strength on the left side over that on the right was a contra-indication. As to Dr. English's paper, he thought that the acid idea had been carried too far and that the auto-intoxication theory cannot be invoked to explain all cases of cardiac irritability. He would object to Dr. Pattee's drug combinations as overdosing. He believed that stimulants are useful, and would prefer whiskey. We must consider the heart

not alone, but with reference to the rest of the circulation. To quiet a nervous heart he had found nothing equal to opium.

Dr. Sears, of Wisconsin, noted the uselessness of heart tonics, so-called, so long as œdema or ascites exists. We must first relieve the latter by purgation or venesection, and then our diuretics will act.

Dr. Chapman, of Louisville, had examined the stomach contents in nearly thirty patients with reference to lactic acid. While this appeared during digestion it should disappear three or four hours after a meal. In rheumatic cases it was constantly found, and he believed that it was this acid which caused the endocardial lesions of rheumatism.

Dr. Charles G. Stockton, of Buffalo, did not believe that heart disease was often caused by acid intoxication.

Dr. G. W. Webster, of Chicago, maintained that Dr. English had made no distinction, in speaking of acid-producing foods, between vegetable and mineral acids. The former are split up in the body and excreted as alkaline carbonates, and therefore could not possibly increase the acidity of the system.

Dr. English denied that the latter fact had been proven.

Toxic Origin of Nervous Diseases.—Dr. Albert E. Sterne, of Indianapolis, presented a communication with this title. He declared that inflammations of both the central and peripheral nervous organs were, in a great measure, due to the effect which certain discovered and undiscovered toxins exert upon them. In some the result is speedy, as in poliomyelitis anterior; in some the toxin is the product of micro-organisms, as in diphtheritic and typhoid affections, while in others the poison is of an inorganic nature, as in lead, arsenic, mercury, and alcohol. It has been the aim of pathologists and neurologists for many years to attribute the lesions of well-known diseases of the nervous system to defects of a congenital nature or to retarded development. Prognosis in such cases must necessarily be unfavorable. An exterior exciting cause is frequently manifest. The following propositions, therefore, can be laid down:

1. We find as sequelæ of affections of known microbic origin inflammations, and, secondarily, degenerations in both the central and peripheral nervous elements. 2. After and during the course of such illness as may be justly supposed to be due to bacterial invasion, we find characteristic symptoms from the side of the nervous system denoting organic disease of the tissues of the system. 3. By analogy we may infer that both of the former classes are due to the effect of the microbes themselves or to the production of poisons by them. 4. This analogy is given by the two following subdivisions: *a*, The inflammations and degenerations found in the nervous tissues as the result of toxins of non-microbic character; and *b*, those notably due to the presence in the nerve elements of micro-organisms or their products.

The writer has examined sections of blood-vessels taken from cases of many of the common nervous diseases. It cannot be said that there was any constant degree of pathological alteration, and yet in all the condition of the vessel walls differed markedly from the normal. The changes seemed most marked in cases of syphilis and in post-syphilitic tabes and senile dementia. All the layers of the arterial coat are affected. In the main the process is one of cell proliferation, effecting increase in the volume of the vessel wall at the expense of the vessel lumen. Even where fragmentation of the vessel walls has occurred, and where the intima or adventitia are loosened from the media, this increase persists. Very often the lumen of the vessels is entirely obliterated just as in syphilitic endarteritis. In several specimens enormous numbers of leucocytes were present in the vascular tissues. In several instances slight hyaline degeneration was present, but not constant or widely diffused. Thrombosis seems more common in the chronic, and fragmentation more usual in the acute, diseases, as poliomyelitis and myelitis. In the cases of scarlatina and diphtheria, which were all rapidly fatal, evidences of acute inflammation and extravasation predominated over all other changes. Fragmentation and varying degrees of tearing and loosening of the various coats also obtained.

In epilepsy and chorea the same changes were noted minus the signs of acute inflammation. The innumerable minute hemorrhages present indicated that some agent, probably toxic, had exercised considerable influence upon the vessel walls. The state of the vascular system in the marantic conditions investigated, namely, the tubercular cachexia, and anæmia and alcohol, showed no great divergence from that described above. It is in syphilis, however, that the vascular lesions are most intense and wide-spread. It may be that different parts of the nervous system possess decided affinity for certain toxic agents.

The discussion was opened by Dr. George J. Preston, of Baltimore. He said that the vascular changes in tabes occurred in an especially interesting and remarkable manner. Cervical tabes was relatively rare and generally secondary. The blood-supply of the lower cord, the usual seat of the disease, was from branches of the intercostal arteries, which were types of vessels easily sclerosed. They were small, and given off at right angles from the parent trunk. Atheromatous material was therefore easily heaped up at their mouths. Hence nutrition to the lower part of the cord is diminished. He had found that nitro-glycerine given early in locomotor ataxia greatly relieved the pain.

Dr. Patrick, of Chicago, was willing to admit the influence of toxic agents on the nervous system in alcohol, syphilis, mercury, and lead. While it must be remembered that all children are neuropathic, he would not go so far as Dr. Sterne in including the changes in the vessel walls as primary lesions. The first alteration is in the nerve-centres. The poison-conveying blood is first brought to them, and the vascular wall changes are secondary. He doubted the correctness of Dr. Preston's views. Tabes is not now regarded as a disease of the posterior columns. The effect of nitro-glycerine don't prove anything. It increases the nutrition of the posterior root zone, and in so far was commendable, but it must be remembered that sclerosed vessels do not readily dilate under this remedy.

Effects of Oxygen.—Dr. George J. Preston, of Baltimore, read a paper on "The Effect of Pure Oxygen Introduced into the Body in Various Ways upon the Hæmoglobin." He first gave a *résumé* of the work of various writers. In his own experiments it was noted that there was for the first few minutes little increase in pulse-rate or rise in arterial tension, but respiration was lessened in frequency. It was a disputed point whether inhaled oxygen gave more oxygen to the red cells than did ordinary air. He had placed animals in a glass jar containing caustic potash to absorb the expired CO_2, and had then turned on a stream of pure washed oxygen from a cylinder. The following results were noted with rabbits:

			Before Inhalation.	After Inhalation.
1.	Time, 5 minutes.	Hæmoglobin....	58 per cent.	58 per cent.
		Respiration	100	200
2.	" 15 "	Hæmoglobin....	52 "	80 "
		Respiration	100	80
3.	" 30 "	Hæmoglobin....	58 "	62 "
		Respiration	100	60
4.	" 60 "	Hæmoglobin....	52 "	67 "
		Respiration	100	35

Similar experiments in dogs gave similar results. A series of experiments was also undertaken with men, to whom the drug was given in the usual manner. The results were as follows:

							Before Inhalation. Per cent.	After Inhalation. Per cent.
1.	Weight,	140	pounds.	Time,	7	min.	Hæmoglobin..	82 92
2.	"	160	"	"	5	"	"	..78 87
3.	"	150	"	"	6	"	"	..76 83
4.	"	190	"	"	5	"	"	..80 95

No special symptoms were noted. There was no exhilaration and no quickening of the pulse, no increase of oxygen in the plasma, but all the red cells seemed to get their full complement of oxygen. During chloroform inhalation, it was found in one instance that hæmoglobin fell from 80 to 68. And Da Costa has found a like thing to exist with ether. In ordinary respiration some red cells do not seem to be fully satisfied. The paper closed with a general plea for the more extensive use of oxygen in lung diseases. It can easily be given by rectal injection.

Lead Encephalopathy.—Dr. A. E. Roussel, of Philadelphia, reported a case of this affection. The patient, an artist, aged thirty years, had gradually run down and become very anæmic. Cells were fifty per cent., and hæmoglobin eighty-five per cent. The second cardiac sound was accentuated and the urine concentrated, but contained no albumin or sugar. Three days later he had an excruciating attack of colic and constipation. Lead was found in the urine and the blue line on the gums. The manner of entrance of the poison was believed to be due to his habit of cleansing his brushes in water and afterward wiping them on his lips. In addition to the gum-line there were patches of a similar character on the inner side of the cheeks, which grew white when washed with oxygenated water.

The patient's condition grew gradually worse in spite of treatment, and suddenly, while walking on the street one day, he fell to the ground unconscious, experienced violent convulsions, and went afterward into a condition of violent delirium lasting all night. It was so violent that a straight-jacket was necessary, and the temperature rose to 101.6° F. The urine was drawn, but no albumin or sugar found. The administration of ether by inhalation was followed by profound sleep, from which the patient awakened after seven hours, fully conscious, and convalescence was speedily established.

The exact cause of these cerebral conditions we do not know. In fatal cases the brain tissue has been found yellowish, hard, and friable, and lead in the cerebral tissues, but the same condition has been noted in other maladies. In many cases of plumbism the anæsthesia and hyperæsthesia and the headaches have been relieved by bromides better than by the iodides. Recent statistics from modern literature show the records of some eighty cases with a mortality-rate of about seventy per cent. The writer has recently seen two cases of asthma due to lead, but there was not the expiratory dyspnœa characteristic of true asthma. The great indication in the head cases is to induce sleep. In lead colic and constipation better results have followed the administration of larger doses of olive-oil than of any other remedy. The pain has ceased before bromides have had time to act.

Typhoid Fever.—The opening paper was read by Dr. J. E. Woodbridge, Youngstown, O. His views on treatment have already been published.[1]

He believed that we could divert death in every case of the disease and that if treatment is begun by the eighth day we could abort every case. His present reports contained the records of fifty-eight additional cases. He declared that there was no doubt as to the correctness of diagnosis, and believed that he had aborted a large number of doubtful cases. He read corroborative testimony from other physicians covering about six hundred cases in all. Of these nine have died. In all the rest the average duration of the disease has been twelve days. He believed that his plan of treatment, in view of his experience in recent years, eliminated the dangers of perforation and hemorrhage and averted all the other dangers of the later stages of the disease. His theory of causation was that the disease was due to a special poison of possibly microbic origin.

The paper above referred to contained in full the remedies he usually employs. They are combinations of calomel, podophyllin, guaiacol, carbonates, eucalyptol, menthol, and thymol. Diarrhœa does not contra-indicate their employment. The result arrived at was complete intestinal antisepsis. As the case improved he left out the calomel and podophyllin and increased the guaiacol. The remedy could be employed in capsule, as the substances given were rather irritating to the mucous membrane of the mouth.

The discussion was opened by Dr. Heller, of Wisconsin, who had tried Dr. Woodbridge's remedies, but he took a general issue with the latter as to their value. He believed, however, that the antiseptic treatment was in the line of rational therapy.

Dr. Uhler, of Baltimore, had endeavored to obtain the same results with carbolic acid in glycerine and sulpho-carbolate of zinc.

Dr. Sykes, of Ohio, had had good results with the Woodbridge treatment. Frequently it has not aborted the disease, but it has changed it to an intermittent or remittent type.

Dr. W. E. Quinn, of Chicago, believed that no one ought to discuss this paper who had not had personal experience with the method. Abortive typhoid is not an unusual occurrence, and the diagnosis must be guarded by a most careful examination of the blood and urine.

Dr. Woodbridge in closing stated that he rarely bathed his patients and gave no stimulants. He does not even order his patients to bed, and allows them beef and steak if they so desire. He generally gives his remedies in capsules, as owing to their pungent nature they are irritating to the mouth and pharynx.

Cholelithiasis.—The next paper was read by Dr. George W. Webster, of Chicago, on "The Differential Diagnosis of Cholelithiasis." Statistics show that ten per cent. of all men, twenty-five per cent. of all women, and thirty-six per cent. of all the insane have gall-stones; but of all these only one per cent. experience any symptoms therefrom. For such patients medicines are useless, and an early diagnosis of their condition is imperative, for they more often need reference to a surgical clinic than a trip to Carlsbad. He divides them into two classes: 1, Those with stones in the cystic duct or gall-bladder; and 2, those with stones impacted in the common bile-duct. In the former, jaundice is the exception, while in the latter it is present and persistent.

In the first variety the earliest symptom is colic. It is referred to the duodenal region, is sudden and of varying severity. If very severe, convulsions ensue. Nausea, vomiting, chilliness, fever, and sweating are all present. The pulse is frequent, small, and soft. Collapse and cramps in the voluntary muscles are not uncommon. Physical examination shows a dilated gall-bladder, while in the second variety atrophy of this viscus is the rule. The tumor is continuous in dulness with the liver and moves with the respiration. Auscultation may reveal the friction sound of the stones moving on each other. If stones are found in the fæces, the diagnosis is certain. They are, however, often dissolved in the bowel. Differential diagnosis lies between gall-stone and lead colic, malarial poisoning, gastralgia, peritonitis, and renal colic. In lead colic there are other plumbic symptoms, as the gum-line, the urine reaction with potassium iodide, anæmia, and multiple neuritis; in malaria the spleen is enlarged, the chills periodical, and the blood shows the plasmodium; in gastralgia there is no fever, no palpable tumor, no reference of the colic to the ingestion of food, and no jaundice follows the attack. Many of the patients are hysterical or neurasthenic; peritonitis gives its own peculiar clinical picture and is not likely to be mis-

[1] See Journal of the American Medical Association, March 30, 1894.

taken for biliary colic; in renal colic the pain is generally lumbar, running down to the scrotum and causing testicular retraction with vesical tenesmus, blood and pus in the urine, but no bile. As to the tumor itself, it must be differentiated from cancer of the head of the pancreas, ecchinococcus-cyst, impacted fæces in the colon, and movable kidney.

Where the stone is in the common duct any operative interference is, of course, a serious matter, though it may be imperatively demanded. Persistent but varying jaundice signifies a movable stone. Colic occurs from time to time, and bile is constantly present in the urine with the general features of cholæmic poisoning due to the degeneration of the hepatic cells. Slight albuminuria may be present with lessened urea and quantity. Excrementitious retention leads to melancholia. Jaundiced urine is convulsive and not narcotic. The stools are scanty and clay-colored. The pulse is slow; there may be septic endocarditis, blood disintegration, low vascular tension, anorexia, and coated tongue.

In the physical examination of these cases we may not detect atrophy of the gall-bladder, though that generally exists. The stone is in the common duct, and this position illustrates the remedial insufficiency of merely anastomosing the gall-bladder with the duodenum. It is wrong to leave the stone *in situ*, for there is danger of its irritating surrounding structures and so leading up to a malignant growth at that part of the gut where the pancreatic and common bile-ducts empty.

The paper was discussed by Dr. John H. Musser, of Philadelphia, who called attention to the prevalent error in most text-books as to cholelithiasis being almost unknown before middle life. He himself believed that such a symptomatic condition might show itself as early as the fifteenth year. He related the case of a young man of twenty-four who suffered from hepatic colic of undoubted nature, who stated that he had been subject to such attacks ever since he was thirteen, though the condition was not diagnosticated in his earlier years. Pain is not constant in biliary obstruction. As to gastralgia, he believed that many cases so called were in reality due to gall-stones. He was inclined to doubt the existence of this condition except in neurasthenics with stomach trouble, in gastric crises of certain nervous disorders, as tabes, etc. As to operation, the indications therefor depended on renal inadequacy and the state of the red cells. When the latter fell below three million per c.mm. structural disintegration proceeded much more rapidly. In one case the number had gradually fallen down to three million and then fell with startling rapidity to eight hundred thousand. Cases of pneumonia had at their onset been mistaken for gall-stones, and *vice versa*. We frequently have in this condition a febrile movement of an intermittent type.

Dr. F. B. Turck, of Chicago, spoke of the differing views of the Germans and the French as to the cause of the constitutional symptoms of cholæmia. The former regarded them as of microbic origin, while the latter declared them to arise from the accumulation of waste products in the circulation, and the latter were undoubtedly right. The urinary inadequacy in these cases could be determined by the centrifuge more quickly than by any other method.

The Wisdom of Physical Examination for Recruits has been Exemplified in France.—Five thousand conscripts, who were passed into the French army three months ago in spite of their physical incapacity, have been discharged within the last few weeks. The extreme severity of the weather has told upon them to such an extent that bronchitis and pneumonia have become prevalent.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.

REPORT OF ASYLUMS BOARD—THE OPIUM COMMISSION—VOLVULUS OF SIGMOID FLEXURE—TUBERCULOSIS OF SACRO-ILIAC JOINT—ENLARGED PROSTATE—INTRA-THORACIC GOÎTRE—RELATIONS OF SEPTIC THROAT INFLAMMATORY DISEASES.

London, May 3, 1895.

The Report of the Metropolitan Asylums Board is rather a serious document from a tax-payer's point of view, for the cost increases at a terrible rate, and it is proposed to build two more fever hospitals, an infirmary for imbeciles, and establish three more ambulance stations. In 1889 the hospital expenditure was £350,000. Now it is close on £600,000. Of course the number of admissions has also increased at a somewhat similar rate, and nearly half the notified cases are now treated gratuitously in the Board's hospitals. The Board boasts that it protects the metropolis from infectious diseases, but when we read of so many thousands of cases being admitted, and remember that these are less than half the number of notifications, it would seem that much remains to be done in the way of protection. In the treatment of these cases no doubt great good has been done, and the Board is to be congratulated on its wise position in reference to diphtherial antitoxin as well as other matters. If the metropolis could really be protected from infectious disease the cost would not be worth discussion, nor would the profession grudge the sacrifice it must make of its income by gratuitous State treatment on such an enormous scale. It only remains to hope that we are approaching with steady if slow marches to the goal of safety.

Let me refer again to the Opium Commission. It is obvious that the conclusion in favor of *laissez faire* has astonished those who were anxious to put an end to the traffic in this drug in India, but the evidence preponderates so greatly against their prepossessions that it will be no easy task to impugn the conclusion. Some discontent is felt, and will perhaps make itself heard, but the judgment of practical men seems to be that the question must be regarded as settled for a long time to come. It is difficult to regard opium-eating as a beneficial practice save in exceptional circumstances, but the report shows that it is a far less injurious habit than alcohol-drinking, and perhaps not much worse than tobacco consumption. No doubt some cases of injury from excess in opium occur, but they are not nearly so numerous as they have been represented.

Volvulus of the sigmoid flexure is rare, and cases treated by abdominal section with recovery of special interest. Dr. F. L. Benham and Mr. Silcock have had such a case, which was duly related at the meeting of the Clinical Society last Friday. The flexure was twisted half a turn on itself. After reduction the wound was closed and dressed antiseptically. There was no peritonitis. The relief from the operation was immediate. A large quantity of fæces passed naturally. There was slight pyrexia. The last stitches were removed after ten days, and the wound was soon after completely healed. The patient was up and about in a month, looking quite well. Only one or two parallel cases have, I believe, occurred in this country, and only nine or ten have been recorded altogether.

Some interesting remarks followed, on the liability of the condition to recur, and on cases having some analogy with this. The President, Mr. Langton, thought incision of the gut an excellent plan to relieve distention, and Mr. A. Lane considered the best plan was to resect the whole sigmoid flexure and join the divided ends. Dr. Benham in reply thought the non-return was due to care in keeping the bowels open. At the same

meeting Mr. Golding Bird related cases of tubercular disease of the sacro-iliac articulation treated by early erasion on the plan he advocated long ago. He urged early operation, as in other tuberculous joints, and said pain elicited by pressure over the root of the posterior inferior iliac spine was a valuable indication of inflammation in the joint. The after-treatment was simple, and the patients were soon about again. One adult could bear his weight and walk about in eight weeks.

Mr. Croft was glad to see early interference in this as in other joints. Years of suffering and incapacity were thus prevented. The abandonment of splints after operation was a further advance. The diagnosis was certainly difficult in the early stage, and he had in several cases been unable to elicit the pain on pressure.

Two cases of castration for enlarged prostate were reported by Mr. Mansell-Moullin, who wishes to call the operation "orchotomy" instead of orcheotomy, as some on your side have done. The Greek verb ὀρχοτομειν signifies to castrate.

Mr. Langton mentioned that many years ago after removal of a senile tuberculous testis from a patient who also had enlarged prostate, that organ diminished in size on the corresponding side. Three years later the other testis was removed, as the tubercle had appeared in it, and this second operation was followed by diminution of the prostate on that side. The patient is now alive and well.

Mr. Gould removed a tuberculous testis from a young man the year before last, and the second testis early this year. After the first operation there was no decrease of the prostate, but a great shrinking after the second.

Mr. Bowlby then related a case of intra-thoracic cystic goitre, causing attacks of severe dyspnœa in a woman of thirty-four years. He evacuated more than a pint of fluid from the cyst at the operation several months ago, and it has not reaccumulated.

At the last meeting of the Royal Medical and Chirurgical Society Dr. Felix Semon read a paper on the "Probable Pathological Identity of the Various Forms of Acute Septic Inflammations of the Throat, Hitherto Described as Acute Œdema of the Larynx, Œdematous Laryngitis, Erysipelas of the Pharynx and Larynx, and Angina Ludovici." He fully stated the reasons which had induced him, in spite of the absence of bacteriological evidence, to submit his ideas on the question of the nature of acute septic inflammations of the throat and neck to the judgment of the Society. He commented on the confusion which existed in the nomenclature of these inflammations. He tried to show that the various forms of acute septic inflammation of the throat and neck, hitherto considered as so many essentially different diseases, were in reality pathologically the same; that they merely represented degrees varying in virulence of one and the same process; that the question of their primary localization and subsequent development depended upon accidental breaches of the protecting surface through which the pathogenic microorganism, which caused the subsequent events, found an entrance; and that it was positively impossible to draw at any point a definite line of demarcation between the purely local and the more complicated, or between the œdematous and the purulent forms. In support of this view he alluded to fourteen cases, two with full notes of post-mortem, and endeavored to answer the objections which could be raised against his views.

Mr. Hutchinson (President) thought Dr. Semon was not making an advance, but was falling back on old-fashioned views, which had not been departed from by some. He was prepared to go further and say that many of these diseases were transmutable. He doubted if œdema was the same as erysipelas of the larynx, but the one might develop from the other; but believed that there was a contagious form of catarrhal laryngitis. He had seen a case of œdema of the larynx which ended fatally, and which appeared to be produced by exposure to cold, and not by septic influences. The influences of these diseases might undoubtedly be intensified by transmission.

Dr. de Havilland Hall and Dr. Sharkey supported Dr. Semon.

Mr. Lockwood said that much would turn upon the sense in which the term "pathological identity" was used; for identity of bacteriological invasion was not necessarily identity of disease. In acute angina ludovici there was a streptococcus invasion, and the same was highly probable of acute inflammation of the pharynx, larynx, and tonsils. An acute abscess of the arm might be due to staphylococcus aureus, and a peritonitis might exist, due to the same streptococcus, yet no one would say that the diseases in the arm and peritoneum were identical; it was necessary that there should be identity in the tissues which were attacked. In these inflammations about the neck and throat, it was improbable that there was an identical bacteriological invasion in all. Fetor was common in angina ludovici, and this was always due to a bacillus. In one case bacilli were found which produced gas, and this could not be considered bacteriologically the same as when streptococcus pyogenes was found. As to the tissues attacked, there was the widest difference; in one case the invasion might be about the epiglottis, and in another about the tissues of the neck. Cutaneous erysipelas of the neck was not angina ludovici, but quite different, and the three varieties of erysipelas differed from each other.

Mr. Buslin said the paper made the subject more complicated than before. Mackenzie, in his work, had included these affections, except Ludwig's angina, under one head, and no accurate description of Ludwig's angina existed. There was no sufficient proof in the paper that these diseases were identical, either in their appearances, their physical structure, their clinical characters, or their pathology. In these diseases very few bacteriological examinations had been made, and very few inoculation experiments performed. Then the paper quoted observations to show that no less than ten microbes might produce the same pathological condition, and ten conditions might be the result of the action of one microbe. After hearing the paper he was more confused than ever.

Mr. Harrison Cripps said that he sympathized with Dr. Semon in his desire for uniformity, but he could not admit that that goal had been attained. Many different pathological conditions might produce a similar affection.

The debate was adjourned to the next meeting.

THE MORTALITY OF CASTRATION FOR ENLARGED PROSTATE.

To the Editor of the Medical Record.

Sir: Mr. A. G. Faulds publishes in the *British Medical Journal* (May 4, 1895) a series of cases of castration for enlarged prostate with results which are so remarkable that, as he alludes with surprise to my statistics, I cannot refrain from comment. He reports five cases of double castration with four deaths, a mortality of eighty per cent. In three of the four mania preceded death. No other explanation of the fatality is given. In the fourth case hemiplegia, followed by death, occurred on the twenty-seventh day. In two other cases his "friend and teacher," Mr. H. E. Clark, did a single orcheotomy, but both these patients died after showing mental aberration. No mention is made of an autopsy in any case. Mr. Faulds's fifth patient was alive at the end of thirty days, but showed no improvement.

Double castration in prostatics is an operation so recent that an accurate estimate of its mortality is not

yet possible. It will, of course, vary greatly with the condition of the patient, especially as regards general atheroma and precedent renal infection. Guyon considers the hypertrophy of the prostate as the result of a constitutional disorder beginning as arterial sclerosis. While I do not accept this theory of causation, the frequent association of the two conditions is a matter of common observation. It is obvious that either with or without operation such patients will often die from hemiplegia and will still oftener die with symptoms associated with various degrees of cerebral degeneration, or with the mental phenomena of uræmic intoxication.

I have no wish to underrate these risks. If I have suggested an operation which will not stand the test of experience the sooner that fact is known the better. But I must protest against such communications as the one in question being regarded as valid arguments at this time. Mr. Faulds asks, after referring to my statistics (gathered from various sources), and to the cases of Mr. Fenwick, "would it not be educative and equally important to give the details of non-successful cases?" It undoubtedly would. The details of a few carefully observed and thoroughly studied unsuccessful cases would probably be of more use just now than larger numbers with better results. But Mr. Faulds's "black list," as published, does not meet the requirements.

In only two of the seven cases is the age given. In only one is the size of the prostate estimated. In two the urine is said to have contained "pus and blood;" no other urinary examination is alluded to. In only one is the amount of residual urine mentioned. The condition of the patient as to general health is not once described.

In other words nearly all the factors upon which prognosis is based have been omitted. Moreover it is stated of these patients that "some had been relieved so far, of bladder and kidney disturbance by perineal section, all with the object of minimizing the immediate and remote effects of the operation." Perineal prostatotomy in such cases has a mortality of its own. It seems to me inconceivable that any one familiar with the literature of the subject should perform it "with the object of minimizing" the effects of castration. It will doubtless often be the operation of choice, and its previous performance need not necessarily prevent a later castration, but the combined operation would certainly have a higher mortality than either prostatotomy or orcheotomy alone.

Double castration is one of the oldest known operations, and when performed in average subjects for local disease or injury is now generally regarded as almost without danger. Butlin estimates the proper mortality of single castration in malignant disease at about two per cent.

I shall shortly publish a complete statement of all the cases I have been able to collect, both successful and unsuccessful. In the meantime I would respectfully ask that a mortality of eighty per cent. for double castration and of one hundred per cent. for single castration be regarded as unusual and unnecessary even in prostatics.

I am sir, yours, etc.,

J. William White.

1810 S. Rittenhouse Square, Philadelphia.

The Women's Institute of Medicine in St. Petersburg, which was closed by order of the government some years ago, is about to be opened once more by command of the Czar. Former students who have obtained their degree will be allowed to practise as medical practitioners.

Food and Drink of Parisians.—During the year 1892 the inhabitants of Paris drank 101,664,190 gallons of wine and ate 3,520,000,000 pounds of meat.

SILVER NITRATE IN THE TREATMENT OF GONORRHŒA.

To the Editor of the Medical Record.

Sir: In the issue of the Medical Record of May 4, 1895, Dr. Frederick A. Lyons advocates the use of a four per cent. solution of silver nitrate in the early treatment of gonorrhœa. In the cases enumerated, unless one examines them carefully, he will fail to recognize an important factor in those cases which made so rapid a recovery. Every one of them had had previous attacks, whereas those cases with which he had so much difficulty were those giving no history of past attacks. It is a well-known fact that "old rounders," who boast of having had gonorrhœa scores of times, seldom visit a physician, and are usually able to cure themselves of fresh invasions in a few days.

The following arrangement of the cases reported will show that the nitrate-of-silver treatment is anything but a success:

		Time of Cure.
Case V.	No previous attack.....	5 months.
Case VIII.	No previous attack.....	4 weeks.
Case XII.	No previous attack.....	6 weeks.

This gives us an average of ten weeks in the treatment of cases not previously affected.

Without going into detail, mark the results obtained in those who had the disease before:

		Time of Cure. Days.
Case I.	Several previous attacks	1
Case XI.	Numerous previous attacks.....	1
Case XIV.	Same as Case VIII. + 1 attack.....	1
Case II.	Numerous previous attacks.....	3
Case VI.	Same as Case II. + 1 attack.....	2
Case III.	Numerous previous attacks..... ...	3
Case IX.	Numerous previous attacks.....	6
Case XIII.	Same as Case IX. + 1 attack.....	3
Case IV.	Two previous attacks.....	6
Case VII.	Same as Case IV. + 1 attack.....	5
Case X.	Same as Case III. + 1 attack	18
Case IX.	Several attacks + chronic urethritis...	6

Giving an average of nearly five days.

From this we may conclude that nitrate of silver may be used where the urethra has gotten into a state of callousness, but in previously healthy urethras the treatment seems not only useless, but rather injurious.

Very truly yours,

E. P. Hershey, M.D.

Denver, Col., May 10, 1895.

PSYCHOLOGY AND THE PRACTITIONER.

To the Editor of the Medical Record.

Sir: The editorial in this week's Medical Record on "Psychology in the Education of the Physician" is interesting because anything that reflects on medical education is interesting, yet the drift of the article turns one's thinking not in an opposite but in another direction. All through the life of a physician the supernatural is expected of him too often, and the result is cant in more senses than one. "If doctors knew more," etc., is only one more instance of "the slender tendrils of the mind, snatching at and laying hold of abstract notions" concerning an ideal doctor of godly proportions and misty configurations. Not long ago a distinguished philosopher told the world that doctors (that is, practical medicine of a scientific type) were too much burdened with scientific principles, and had too little real knowledge of what will help to prevent failure in their careers. When saying all this, Hartmann took in things from the outside, and not from an elevated or elevating stand-point. Like Marshall he is an outsider and really does not know, and is dealing with abstractions, and not with a condition of affairs, as they are, or can, or may be. Anything that cannot be understood or put into action may be said to be an abstraction. How is it possible for doctors to be everything that every-

body—the doctors often included, and too often—say they should be? The other night at a dinner a medical professor claimed that the practitioner in our day must be more than a dispenser of advice, drugs, and remedies to his patients, and he set the clown's cap on all his proud words by pointing to Koch, "the country practitioner."

Perhaps Koch was studying psychology and psychiatry and all the other ologies while he was hunting for bacilli and almost starving for want of practice. Koch had mental bias, like all of us, and he had the mental force and quality to do it justice, although bread and butter was his object; and, just because he failed in bread-and-butter pursuits he succeeded as a scientific discoverer. High ideals of what the general practitioner ought to be did not help Koch to lay hold of the bacilli he discovered, but his training plus his bias, his likes, and whims did. Now, Mr. Editor, only the other night some of us doctors, who graduated fifteen and twenty years ago, were speaking of the methods according to which we were taught, and of the superior training the students of to-day were put under. And yet our time was fully occupied in accumulating the knowledge that we were obliged to consider necessary to the making of a doctor. And what more can be expected? The conscientious student of to-day has no time to waste in spite of better methods. We certainly have not outgrown the facts of time and place; and these facts deserve consideration in the fixing of what the student of medicine as a candidate for the rights and honors of practitioner of medicine (for that is what M.D. means) ought to be examined on.

The student ought not to be overburdened! And unless godly homage is what doctors may claim as a right, godly attainments must not be expected of them!

Bismarck is an exceptional man, and he is that because he understood the give-and-take qualities of human nature; but what does Bismarck know of "the modern principles of psychology"? Bismarck brought his psychological insight with him when he entered the political arena—he was born with it.

Modern psychology is analytical, and very full of hypotheses; but as knowledge it is good, and we doctors do not mean to deny it recognition and cultivation.

What some of us do protest and struggle against is being overcharged with principles that we should bring with us to our medical studies, and not be obliged to stand in fear of some examiner's interpretation of principles concerning which differences of opinion exist, and which do not help us "to deal with the problems of errant human nature." Let us cultivate all the ologies, let us develop science and the scientific investigator, but let us cease placing the practitioner in a false light by reflecting the faint glimmerings of whimsical abstractions on him and exhorting with all the power of rhetoric unknowing laymen to believe that candlelight is better than daylight illumination. A sponge will absorb just so much and no more, no matter how big the tub may be into which it has been thrown. So don't drown your poor student. Medical psychology comes with medical study and practice.

Adolph Rupp, M.D.

406 West Thirty-fourth Street,
May 25, 1895.

A Frightful Remedy for Coryza has been proposed by a certain Dr. Maurel. He advises the introduction into the nostrils of a pledget of cotton impregnated with iodoform powder, and also that iodoform lozenges be allowed to dissolve in the mouth of the sufferer.

Bicyclers are not allowed to ride in the streets of Berlin, as they are in most cities, and now names are being collected for a petition to the authorities to make the streets accessible to them.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending May 25, 1895.

	Cases.	Deaths.
Tuberculosis	94	128
Typhoid fever	9	2
Scarlet fever	93	7
Cerebro-spinal meningitis	0	0
Measles	297	32
Diphtheria	225	30

Foot-and-mouth Disease has been quite prevalent in Berlin during the past winter, and there have been a number of cases in the human subject.

Vaccination and Confirmation.—Archbishop Walsh, of Dublin, has recently issued instructions to the clergy of his diocese to the effect that no one shall be admitted to confirmation or instructions in preparation for it who has not been vaccinated, or who, having reached the age of seven years, has not recently been vaccinated.

The Three Most Common Diseases in California are tuberculosis, cancer, and rheumatism.

Hospitals on Wheels.—It is proposed to build some travelling hospitals for infectious diseases to be used in sparsely settled places in the north of England.

The Beaven Rake Memorial.—The subscription list to this fund has now been closed. It has been decided to spend part of the money in the erection of a memorial tablet in Guy's Hospital Medical School, and to hand the balance to Dr. Rake's widow and children.

The Latest Sensation in Paris is the alleged discovery by a M. Groussier of an infallible law whereby the paternity of children who have no acknowledged father may be ascertained.

The Three Causes of Women's Diseases.—Dr. Balls-Headley finds in our social system three great causes of disorder of the female generative organs: Mental culture, by which physical development is often sacrificed to mental training; female dress, the faults of which it is needless to particularize; and unsatisfied sexual desire. The latter includes, of course, the unsatisfied desire for maternity. In civilized communities more than half the women under thirty years of age are unmarried; in other words, the sexual instinct, during the first half of its existence, is in most women ungratified. Hence spring, in Dr. Balls-Headley's opinion, many sexual disorders.

A Russian Censor on Mushrooms.—The Russian censor Korasovsky once erased from a book on natural history the chapter treating of the noxiousness of fungi, on the ground that "fungi form the favorite food of devout Christians on fast-days, and whoever declares them to be noxious seeks to undermine the Christian faith and to diffuse irreligion."

Professor Bunsen, the noted chemist, famed for his discoveries in spectral analysis and other scientific matters, celebrated his eighty-fifth birthday on March 31st. He gave up teaching five years ago, but still lives at Heidelberg in excellent health.

The Fee for a Professional Visit in Nottingham, England, is one shilling, according to a correspondent of the *Medical Times*. Even then the medical man often has to take it out in trade with the small shop-keepers, who refuse to pay such exorbitant charges in cash.

ON THE CONSEQUENCES OF HYPERÆMIA AND THE PATHOLOGY OF INFLAMMATION AND SUPPURATION.[1]

BY ROSWELL PARK, A.M., M.D.,

PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF BUFFALO.

THE writer's purpose in presenting at least the first part of the following paper to the Fellows of this Association is avowedly and distinctly to challenge or to provoke kindly criticism. I purpose to take up a presentation of some of the elementary topics in surgical pathology which are dealt with in general treatises and in students' text-books, usually in the opening chapters, and to endeavor to show that in our presentation of these subjects we have been usually inaccurate in expression and incorrect in our teaching of elementary pathology. If now, I am right in this, then there is sufficient reason for alteration in the method of teaching and improvement in subject matter of the same. On the other hand, if I am wrong and it can be so shown, it is not likely that I shall again tax your patience with anything of the kind.

Purely mechanical and traumatic disturbances and the surgical infectious diseases, more particularly the local manifestations of the same, have about the same apparent beginning, that is, in either case there are certain local phenomena which follow more or less a classic order, their character being, in either case, the same in gross appearances up to a certain point, after which there is the widest possible variation in local manifestations and in systemic complications. In time past all these manifestations have been grouped under the general term of "inflammation," and we have been taught that inflammation at one time is congestion with slight exudation; at another, hyperæmia with copious exudation; at another time, that it leads to pus production; and that at yet another its final result is hyperplasia and tissue new formation with more or less induration. These widely different terminations have provoked the introduction of certain adjectives; and hence we have had described "simple inflammation," "acute inflammation," "infective inflammation," "chronic inflammation," etc. My thesis now is that the term inflammation ought to be confined exclusively to one distinct class of lesions, namely, those produced by micro-organisms, and that for other lesions into which the question of infectious micro-organisms never enters, be they acute or chronic, mild or destructive, the term "inflammation" should never be applied, but that we should call such lesions what they really are, that is, that the name applied should be based upon the pathological lesion.

It is well enough to say that all inflammation begins with congestion, which may be true; but there are very many congestions which never terminate in genuine inflammation, and I would prefer rather to describe congestion as something which may be provoked by certain exciting causes, of which bacteria may be one, in which case the congestion itself is subsidiary, and in a measure accidental or conservative. Or, rather, I will make myself more plain as follows: Let us suppose a mechanical disturbance such as has led, for instance, to a violent sprain of the knee-joint. What phenomena do we note? The old *calor*, *rubor*, *dolor*, *et tumor* of our forefathers, along with disturbed function, which signs increase in intensity up to a certain point, when the process seems reversed and manifestations fade away in inverse order. What does all this mean? That there has been dilatation of vessels with active escape of fluid from the same into the cavity of the joint, and to some extent perhaps around it; that the redness is caused by the hyperæmia, the pain by the tension and pressure on nerves, the heat by the same cause as the redness plus some more active chemical change, and the swelling by the escape of fluid into previously existing cavities, fluid which has leaked from the vessels, as is well known it may. Let everything go well and this fluid is quickly taken up by the absorbents, veins, and lymphatics; the vessels return to their natural size; the pain and redness and swelling subside, save for perhaps a little chronic thickening of the parts, which may last for a considerable time, and which represents a too great amount of actual cell activity or proliferation around the area first involved, activity which is, in large degree at least, conservative. Here now we have had the phenomena of hyperæmia, exudation, and resorption, the first due to traumatic influences, the last to the conservative powers of the system.

I maintain, then, that the redness and heat should here be spoken of as evidences of hyperæmia, that the swelling should be described as due to exudation, and that this may be more accurately described, and that the speedy resorption should be pointed to as evidence of the speedy subsidence of the irritation which first provoked the diseased condition, *i.e.*, of the fact that the cause had ceased to act, and that it should all be regarded as an expression of reparative power, which, however, may perhaps have gone to excess, perhaps even to absurd degree, permitted to take this course partly by constitutional causes, partly by lack of proper treatment. And I maintain further that this should not be spoken of as "inflammation." But let now this exudate have become infected from any source, the question of source not now being that under discussion, but in a general way, be it from within the body or from without, and let micro-organisms once secure access to the parts within, and how quickly is the whole clinical picture changed! Now we have not only formation of pus and the condition which we would speak of as purulent synovitis or pyarthrosis, but we have unmistakable, perhaps serious, perhaps even fatal constitutional disturbances, all of which go to indicate the serious character of that which has begun in the joint. This now deserves the name of "inflammation," in fact, this is inflammation, and is a condition as different from that portrayed just before as is storm from calm. It is, in other words, a condition of congestion and exudation plus the specially disastrous characteristic, infection. Without infection, no genuine inflammation; with infection, inflammation, and what always goes with conflagration, more or less destruction. Congestion and exudation practically never lead to destruction; inflammation always does. Congestion and exudation provoke little, ordinarily no constitutional symptoms; inflammation always does. Even

[1] Read before the American Surgical Association, May 30, 1895.

from a trifling furuncle on the nose one may have an elevation of two or three degrees of body temperature.

I have said above that congestion and exudation never produce destruction. Rarely they do, but by pure accident of location and by mechanical activity. This may occur through intensity of active exudation, or by loss of tissue irritability and contractility, which permits enormous passive exudation. Or, to put it in another way, stagnation of blood may permit gangrene, although even here moist gangrene is a question of infection, but in another way and from another source. We have also the hyperæmia of paralysis and the hyperæmia of irritation; but most of the cases of gangrene with which we have to deal, being practically only those produced by intense heat or cold, or by pressure, are due to the intensity of the infectious process, which includes exudation, but includes much else that is not comprised within that term.

I think we cannot go far wrong in this matter if we accept the definition of inflammation proposed, for instance by Metschnikoff, which is in effect as follows: Inflammation generally must be regarded as a phagocytic reaction on the part of the organism against irritants. This reaction is carried out by the mobile phagocytes, sometimes alone, sometimes with the aid of the vascular phagocytes, or of the nervous system. The irritants herein alluded to are, of course, micro-organisms. This definition is based on a comparative study of phenomena presented by living cells when exposed to such irritation and studied in the lowest forms of life, as well as in others higher in the animal scale. It is necessary to emphasize the fact that the essential phenomena of inflammation represent an actual struggle between the phagocytes and the irritants, or, as Virchow has aptly termed it, a battle of the cells, and that pus and pus cells represent simply the débris, and are really the dead bodies of animal cells which have perished in the struggle. As Metschnikoff has pointed out, some of his critics, like Franco, for instance, have claimed that this phagocytic theory presupposes extraordinary powers on the part of the protoplasm or the cells which are to become the phagocytes, and to which are attributed sensation, or a kind of psychical activity. But that the animal cells possess some such activity has been shown by many observers independently, and the name coined in latter years, "chemiotaxis," has been designed especially to recognize and make plain this fact. The explanation for the peculiar attraction between bacterium and cell by which the latter endeavors to become a phagocyte is probably as remote as it ever was; but, be this as it may, the action is unmistakable, and phagocytosis is no longer a term, nor a fiction of the imagination, but is a proven fact.

It does not do to say that inflammation is a reaction of the organism against injurious agents and nothing else; since, if this is the case, it often happens that the phagocyte refuses to act just when the organism is most threatened. The law of phagocytosis is but one expression of the law of natural selection. Still, to pursue this interesting train of thought would take us too far away from the primary object of this paper.

Let me now propose to you some such basis of text-book arrangement and classification as follows: I would begin with hyperæmia and congestion, which we may consider for present purposes as synonymous, and would speak first of the physiology of the blood-vessels and the control of the vasomotor nerves, and would show how temporary alterations in the circulation of a part may be determined by even trifling or purely temporary causes. I would show, for instance, that a mild degree of hyperæmia may be perpetuated for a considerable length of time without other perceptible alterations, and that such changes are largely under the control of the nervous system. I would show, next, that in the presence of minute tissue lacerations or disturbances, such as may have been produced by a great variety of mechanical causes, such as are comprehended, for instance, in the conditions called "sprain," "frost-bite," "burn," "chafing," etc., that there are more active changes in the direction of increase in size of the vessels, engorgement of the part, stagnation of blood-current, cellular activity outside the blood-vessels, escape of blood serum, which literally leaks out from the vessels whose walls are put upon the stretch, or at least the cohesion of whose walls has been affected, and that in the presence of certain favorable surroundings, as in loose connective-tissue, or into normal cavities, such serous out-pour may be excessive. I would show next that along with this may go pain and the other unmistakable objective evidences by which a diagnosis is easily effected. Then I would show that this was to be clinically regarded as an excess of effort in the right direction for repair of damage, and that the efforts of the physician should be confined to control of these manifestations within certain reasonable limits. Next, that within a certain length of time a subsidence of these phenomena may be expected, which are to be explained by the re-entry of escaped fluid elements into the circulation, by the gradual restoration to normal size of the enlarged blood-vessels, and that some thickening or permanent manifestation may be looked for if the process has been more than very temporary, because the longer it goes on the more actual cell activity there is with tissue new formation. To this there should then be added that under certain circumstances exudation may occur so actively that the integrity of surrounding parts may be threatened, and that it is well sometimes to interfere, as with scalpel or aspirating needle, in order to relieve tension.

Then I would go on to show that under certain other conditions the acute disturbances thus set up subside only to a certain point; after which there appears to be cessation of retrograde phenomena, as the result of which there is maintained a condition of slight hyperæmia and of tissue-thickening which may persist for a long time, as well as the results of the same in the character of undue sensitiveness, pain, etc. These are the phenomena ordinarily spoken of as chronic inflammation, which in this scheme should be described as hyperplasia due to previous cell activity.

Again, I would speak of certain other changes which are due to mechanical disturbances or irritation so trifling in degree, but so continuous in persistence that by very gradual changes there are brought about conditions in which we recognize tissue new formation with, perhaps, pressure effects upon vessels, etc. In other words, I would group under these heads the phenomena often spoken of as "cirrhosis," or as chronic inflammation which was never anything else—*i.e.*, which never had an acute beginning. And in this connection I would show that the irritants which produce such effects are sometimes chemical poisons circulating in the blood—such as alcohol, uric acid, etc.—and that under the influence of certain unknown poisons—*e.g.*, that of syphilis—similar effects can be produced.

Finally, I would in an entirely distinct chapter, and in an unmistakably separate way, take up the matter of inflammation—*i.e.*, infection—and would endeavor to show that *pari passu* with the extent of invasion we have an exceedingly speedy evolution of hyperæmia with exudation, which now, for the most part assumes the solid form—*i.e.*, that the albuminoid constituents of the blood-serum quickly coagulate in the presence of the micro-organisms, and that in consequence of the presence of these minute irritants there is a most lively activity on the part of certain corpuscular elements circulating within the blood and found in mesoblastic tissues, which at once assume the rôle of phagocytes and make their way or are carried to the scene of activity as speedily as possible, when the scene quickly becomes a veritable battle of the cells, in which the invading enemy—*i.e.*, the bacteria—wage a tiny war, to a certain

extent somewhat after the fashion of savage tribes, by using poison—*i.e.*, by producing toxines and ptomaines—and that the question of survival of the tissues involved, or of the organism at large, is practically summed up in the question of its endowment of vital resistance and of the fighting properties of its component cells. In case the invading micro-organisms are conquered, the battle-field is known as an abscess, or as an area of purulent infiltration, with more or less sacrifice of tissue. Whereas, in case they conquer, there is very extensive destruction of tissue, or else there is loss of life on the part of the larger organism thus invaded. Or, to put it another way, a local abscess or its equivalent shows the site of a single battle-field on which the pus represents the cells which have perished in our defence. On the other hand, the symptoms which are everywhere recognized as constituting septicæmia or pyæmia, indicate that the invasion has been wholesale and along numerous different lines, and that the miniature conflict is being repeated in many different localities within the human body; while death is an expression practically of a victorious invasion and consequent famine, tissues which have not been actually conquered being practically starved to death or poisoned.

I would then take up the matter of pus-formation in both its pathological and clinical aspects, but first in the former, and would enlarge upon the fact that it is never produced as the result of hyperæmia alone, but requires always the invasion of certain micro-organisms which act as specific irritants, which practically always determine a very lively "battle of the cells," this being the result of most active migration of leucocytes and wandering cells and their enlistment as phagocytes.

Of the various substances known at different times or known collectively as pus, I have elsewhere treated at length (see my Mütter Lectures on Surgical Pathology), but desire again to call your attention to certain differences which I insist upon should be made, if for no other reason at least for scientific accuracy. I maintain that it is very unfair to consider the discharge from a healthy granulating surface, which is nothing but excess of formative material gone to waste, and which is so often called pus, in the same light with the contents of a circumscribed or diffuse collection of pus due to staphylococci, streptococci, or other obligate pyogenic organisms. Study for a moment what they have in common and how they differ. The material from a granulating surface consists of excess of cellular elements which have been formed by parykinetic proliferation of pre-existing cells, in some measure by emigration from the blood-vessels, but in large degree by multiplication of connective-tissue cells while in their active state. These are sent to the front, as are fresh soldiers in battle, for the purpose of forming new tissue. Nature does this thing usually in excess, and under the stimulus of health and various external applications there is much more cellular activity going on everywhere than these rapidly growing tissues can avail themselves of. Consequently waste material is discarded, and may easily become contaminated with organisms from the surface, which may thus be found in it, and yet that may be in no wise concerned in its production. Such material is almost harmless, and is but little more than a mere nuisance or annoyance. Moreover, when we find so much material, we usually find that it is an expression of some cessation of cell activity, and means that granulation—*i.e.*, repair utilization—has stopped. In other words, such material is, in some measure at least, an expression and index of activity of reparative processes. It lacks ordinarily all infectious properties. How different pathologically, if not in gross resemblance, is such material from that found in an acute phlegmon which is due to bacterial activity, and where now every so-called pus-cell represents a leucocyte or a connective-tissue cell which has perished in the battle of the cells, but which has died fighting nobly, grasping or having incorporated into itself the body of at least one of its enemies, sometimes several bodies. I grant you that the materials from the two sources may look much alike, but I think there is no one who will contend that they are even essentially the same, because one is actively poisonous and infectious and harmful, and needs to be gotten rid of as soon as possible, while the other is harmless and is simply an expression of nature's having overdone a good thing.

From both of these I would differentiate again a material which belongs always rather with the former substance than with the latter, namely, an exudative substance, in large measure a solid exudate, found in drainage-tubes and underneath air-tight dressings, where an absolutely aseptic course of wound-healing has been maintained. This is the material which sometimes fills up and in a large measure plugs a drainage-tube. It is the filmy-like layer which may be found underneath a piece of green silk protective, for instance, which has been placed over a surface where, perhaps, we have been making a skin grafting. It represents, as in the first example, a quantity of good reparative material which has been furnished in excess of the actual requirement. Later, bacteria enter and contaminate this, and it becomes at once like ordinary pus. So long, however, as it be kept free from bacteria it forms only a gelatinous mass or film, harmless, but responding quickly to the slightest invitation to infection.

Fourthly, I must further draw your attention to the material found in old abscesses and breaking-down foci of various infectious diseases. This is known frequently as pus, although it is notorious that all of its infectious properties have been lost and that it has almost, if not quite, lost the toxicity which it had once had, while its microscopic elements have undergone more or less change by chemical processes like calcification, caseation, etc. The surgeon of the past generation, opening an abscess of this kind, of, say, two years' duration, would still speak of its contents as "pus."

Now I maintain, and I am sure I am right in maintaining, that if these substances differ in composition, and especially in properties, it is not fair to call them all by the same name. And so, with not a little diffidence, but an insistence that I am right, I venture to propose to you the following names: For material produced in the course of an acute phlegmon, infectious, toxic, in every way undesirable, I would preserve the good old name "pus," which has fixed itself too firmly in our nomenclature to be abandoned. For material which comes from healthy granulating surfaces, or from raw tissues which have not yet had time to granulate, which is free from bacteria and has no infectious nor toxic properties, I have elsewhere proposed the name of "pyoid" or "puruloid." Finally, for the contents of old cold abscesses which have long since lost everything except the grossest and crudest resemblance to the pus which it may originally have been, or perhaps never has been, I venture the name, with hesitation and yet with good reason, of archepyon. It may be that these names will never creep into general literature, in fact this is quite likely; and whether they do or not matters but little to me so long as there does creep into the minds of surgeons and pathologists generally, exact notions regarding the actual differences between substances heretofore confused under a single name.

Is there anything in this beside straining after accuracy? It seems to me that there is, and especially so in these directions: The treatment called for in the presence of these different conditions is distinct and unmistakable, and would be unfortunate in either of the other conditions. For instance, for real, genuine pus we need the promptest possible evacuation, which may be based or formulated upon the following rule, to which I know of no exception, *i.e.*, that such pus left alone will do more harm than can the knife of the

surgeon if judiciously used for its evacuation. Pyoid or puruloid material betokens a condition that calls for little or no special treatment. Absolute cleanliness is practically all that is needed. Lastly, the presence of archepyon indicates a condition calling for extirpation of infected tissue, for complete and final disposition of that membrane known formerly as the pyogenic membrane, for eradication of all infected tissue, final disinfection of the cavity, perhaps cauterizing of its surface, in order to be sure of our work, and the deliberate provoking of the granulating process, or else the deliberate attempt to secure union by primary adhesion.

And this leads me to speak for a moment of this so-called pyogenic membrane, this being another misnomer which I have fought and shall contend against with all my might. If pyogenic means anything it means pus-producing, whereas the limiting membrane of old or cold abscesses is anything but pus-producing, but is the result of organization of cells and tissues into a dense and resisting membrane, which shall, so far as such tissues can, resist the encroachments of the degenerative process. What is such a membrane but pus-protective, or protective as against pus? This fact, I think, is generally accepted; yet men go on using the old term in spite of its contradictions. For this membrane I have suggested a name, which, I think, would quickly become acceptable to you did you use it, namely, "pyophylactic" membrane, which at once defines its purpose and does not encourage ignorance of pathology.

One or two very practical questions may properly be raised in connection with pyophylactic membrane, and with the statement of its purpose and effect thus implied in its name.

When this is met with in the average cold abscess, it is now the custom of most surgeons to extirpate it. There can be no doubt but that its complete extirpation is the speediest way of healing the entire lesion; and when this is possible it should be effected with precision and rapidity. This cannot always be done, however; and the first question, therefore, to be raised is, Is incomplete extirpation better than nothing, or does it expose to additional danger? Many of these abscesses are so complicated in shape and extent, and contain such prolongations, which are yet lined with this membrane, that they cannot be safely, or at least not wisely, followed by the surgeon. Under these circumstances it seems to me that the best course to pursue is that which I have always endeavored to practice, namely, to excise so much as one can make proper access to, and then, by the introduction of some caustic material, to destroy the balance of the membrane, and thus to effectively dispose of it by destructive measures, if not by extirpation. For this purpose I almost invariably resort to a solution of chloride of zinc, usually of fifty per cent. strength, with which the sinus is mopped out after being curetted; or in case the curette cannot be made to follow it, with which the sinus is injected. This destruction is not so ideal as that which might be effected by the actual cautery, perhaps not by nitric acid, but is efficient for most purposes. One avowed object underlying all this treatment is based upon the fact that this membrane sometimes contains tubercle bacilli which have been lying latent therein, and which may serve as excitants of further disease. After giving this caustic a little time in which to do its work, the parts are flushed in order to wash away that which might do undesirable work; after which I prefer to pack these wounds with some material steeped in a mixture of balsam of Peru and guaiacol, in the proportion of ten to one, to which iodoform may be added if desired. The objection that the caustic acts on fresh surfaces as well as old ones is not a valid one, but shows a condition desirable rather than otherwise, since the possibility of absorption of such germs from these fresh, raw surfaces is thereby removed. As the result of the action of the caustic granulations spring up from every side, and the later result usually is union by adhesion of these surfaces.

If there be any validity to the statements above made, there is every reason why, when a cold abscess is simply incised without effort to extirpate its membrane, the edges of the incision should be cauterized to prevent possibility of fresh infection; and that this is good practice no modern surgeon denies. More than this, the dread which surgeons in time past have shown, and which has been more than shared by the laity and the profession generally, of fresh accession of tubercular disease after incisions of rectal fistulæ, was one for which there used to be some justification, since we now well know that most of these fistulæ are practically tubercular cold abscesses, and that when treated by simple incision and nothing more, a fresh surface is exposed to a focus of old disease, and infection perhaps invited. But if such a fistulous track be thoroughly dissected out, or be thoroughly cauterized, so that all infectious organisms be destroyed, there cannot be the slightest objection to operating on tuberculous subjects for relief of this condition.

What becomes of the pyophylactic membrane if not treated by extirpation? Undoubtedly, it is gradually made away with, if not rapidly, by granulation tissue, the process being a complex one of removal of its component parts by phagocytic action and substitution of granulations therefor. This, however, must be provoked by the stimulus of some foreign body—for which purpose we now mostly use gauze packing—and is liable to interruption or to complete cessation, with possibility of reinfection from organisms yet alive which it may contain. The ideal method of dealing with this membrane, then, is its complete removal; next to this, its complete destruction by caustic agents; and, when neither of these two measures is practicable, the application of antiseptics and stimulating substances to it.

And now it is necessary, in order to complete the paper I have been requested to prepare, to devote at least a little attention to the specific irritants which provoke true inflammation, or which determine the conversion of a simple exudate into pus.

A few years ago, when I published the "Mütter Lectures on Surgical Pathology," given before the College of Physicians, of Philadelphia, in 1890–91, I took particular pains to make as sharp a distinction as circumstances would permit between the obligate and the facultative pyogenic bacteria—a distinction in large measure arbitrary, yet, as I held and still hold, clinically justifiable, and one which I am glad to see other writers and teachers now maintaining. These terms need but little definition. Among the obligate pyogenic forms, I place those whose function it seems to be solely to set up septic disturbance and produce pus—this constituting the whole measure of their pathogenic activity. Of course, I do not mean to imply that they are never found, except in the presence of pus, because investigations of the past few years have taught us that under favoring conditions of tissue vitality even the raw surfaces of wounds may resist their attacks. This does not destroy the validity of my statement just made, however, since whenever they exert any deleterious influence it is in the direction of pus-formation.

On the other hand, there are numerous bacterial forms whose presence is occasionally associated with pus, in whose formation they appear to have played the chief rôle, while it is well known that they may have other activities or actions as well, and that they are not necessarily, perhaps not even frequently, pyogenic.

It is well, for more than one reason, I think, to insist upon these differences, since simple comparison and scientific accuracy are not the only desirable features in making such a classification. It is not my desire here to detain you with long descriptions of these organisms, but rather to briefly catalogue them and assign them their proper positions.

The Obligate Pyogenic Forms.—By common consent we all now place first under this head the various staphylococci—namely, the S. pyogenes aureus, albus, citreus, epidermidis albus, etc., the aureus being commonly the most virulent of all, but each variety showing a variable degree of virulence, according to circumstances which are not always apparent or intelligible. One of the marked characteristics of the staphylococci as a group, containing several species, is the powerful peptonizing action which they may exert. Moreover, the chemical products of their life changes seem to be more potent, both in a local and a general way, leading to greater destruction of tissue in their immediate vicinity, and inhibiting the chemotactic powers of the leucocytes—*i.e.*, phagocytosis—by which their progress would be interfered with.

Next come the streptococci, or at least all of them which have pyogenic properties, since when these organisms manifest any pyogenic activity they do it usually in an unmistakable way. If scarlatina prove, as maintained by Babes and others, to be a modified streptococcus invasion, the microbes which produce it must be placed in another biological class than those which produce suppuration. Confining ourselves, however, to the latter, we may say that they manifest a very strong predilection for lymph tissues and lymph spaces, along which they extend themselves with great rapidity. The streptococci have much less of peptonizing power than have the staphylococci; and these two facts together serve to explain the clinical manifestations of streptococcus activity, which assumes usually the type of purulent infiltration rather than that of distinct and circumscribed purulent collection. Moreover, Cheyne[1] suggests the manner of growth peculiar to the streptococci may have much to do with their more frequent association with pyæmia, since they tend to grow in long chains which may coil up and entangle blood corpuscles; as the result of which emboli may form more easily and become more tenacious wherever they may lodge.

Whether the streptococcus of erysipelas is essentially a distinct variety from the streptococcus pyogenes is very doubtful; in fact, I think it is now maintained by few, although we are not yet in position to say just what circumstances determine streptococcus invasion shall take the clinically more or less distinct erysipelatous type or not.

Staphylococci and streptococci both have the power of producing lactic fermentation in milk, and it is quite sure that lactic-acid formation takes place sometimes along with suppuration in human tissues, causing acidity or discharge, and in abscesses causing watery pus. So far as known also, these two pyogenic forms have less power of ptomaine or toxin formation than many others; consequently, fever-engendering suppuration is not always to be ascribed to this cause alone, for, as Baumgarten has suggested, fever may be due to tissue metabolism due to their growth, the metabolic products thus formed being perhaps pyretic. This hypothesis may be perhaps supported by adducing the fever which occurs in trichinosis, where the question of ptomaines has not yet been raised.

A question which is still unsettled, and which it would appear to me of very great importance to clear up as soon as possible, is the relation which cases of cellulitis, or kindred disturbances which are often confused under that one name, bear to unmistakable erysipelas. Most clinicians would make a distinction between erysipelas, of the skin, for instance, and cellulitis following an injury; and from both these conditions dermatologists like Hebra have differentiated what he called "erythema exudativum multiforme." And, again, Rosenbach has described a cutaneous disease which he has termed "erysipeloid," or "finger erysipeloid." In almost any of these conditions pus may be produced, and yet is not necessarily so in one of them, at least it does not appear in such a way as to be recognized or call for interference. I am well aware that no little study has been given to these conditions, and in the lectures above alluded to I have paid some attention to the results of the same and have given references, and yet to-day, five years later, cannot say that we can speak much more definitely than I did then. Different observers have found different organisms, and various students of the clinical side of these conditions have assured us that so much depends on the general and local conditions of the particular patient, which yet are hard to recognize and equally so to describe in words, that I fear it will be some years yet before we clearly discern the light which I hope may be shed upon this subject. It may be worth while to remind you that the streptococcus which produces the contagious mammitis of cattle, and which may attain extraordinary length in chains, appears to have pyogenic properties in the human race. With both of these organisms, staphylococci and streptococci alike, it appears that their virulence can be increased by passing them through animals. Here one meets with one of the many contradictions of bacteriology, since the very method which usually weakens micro-organisms in these instances seems to strengthen them.

Behring has offered a general classification of streptococci which has much about it that is suggestive. He makes first a class

"A. Of streptococci which attack mucous surfaces and produce certain phlegmons, pneumonia, puerperal fever, and various other lesions of serous surfaces.

"B. Streptococci which produce scarlatina and severe pyæmia. And

"C. A variety which attaches itself in large masses to the infected surface, the best illustration being perhaps in pneumonia of the horse."

Marot, writing in 1893, divided streptococci into two principal groups:

1. "Those whose growth upon potato gives no easily apparent surface marking, namely those of erysipelas, puerperal fever, scarlatina, phlegmonous, and pseudo-membranous angina, the streptococcus murisepticus, the pyogenic form of Rosenbach, the strepto-pneumococcus, etc. And,

2. "Those whose growth upon potato is easily seen, namely, those of normal saliva, of broncho-pneumonia, of simple angina, etc."

Finally, Paschale has proposed a classification into four groups, according to the temperature conditions and culture appearances:

1. "Short streptococci, saprophytes: *a.* Growing at ordinary temperature, *e.g.*, streptococci of fæces and of the skin. *b.* Growing at temperature above 37° F., streptococci of the mouth and respiratory tract.

2. "Long streptococci, non-pathogenic: *a.* Growing at room temperature, those from the intestinal canal, particularly the streptococcus coli gracilis. *b.* Growing above 37° F., streptococci from the mouth.

3. "Long streptococci, pathogenic: *a.* Growing at room temperature, those of erysipelas, suppuration, pneumonia, diphtheria, scarlatina. *b.* Growing above 37° F., certain forms met with in the saliva.

4. "Short streptococci, exceedingly infectious: *a.* At room temperature, the diplococcus pyogenes. *b.* Above 37° F., the strepto-pneumococcus."

Next to the forms above mentioned, I will speak of the pneumococcus of Fraenkel, of Pasteur, and of Sternberg, which seems at times to be a very active pyogenic agent. It is known to be capable of producing, for instance, septic meningitis, and has been found in brain abscesses; it is a frequent active agent also in producing empyema, and may be found under various other circumstances. In inoculation experiments it usually shows quite active pyogenic properties.

The Colon Bacillus.—I will not detain you long with this organism, since two years ago I presented a paper upon this subject before this Association, and because

[1] Treatment of wounds, ulcers, and abscesses, 1894, p. 14.

since that time numerous other observers have noted the same variations in virulence and diversity of location in which this organism may be found. I would simply wish to reimpress the fact that it is, in all probability, identical with the bacillus pyogenes fœtidus of Passet and with the septic bacillus from the urine, of Clado. It figures, not alone as the active agent in most cases of appendicitis with pus formation, but as a frequent cause of septic peritonitis not connected with the appendix; in abscesses in and about the liver and biliary tracts, even in abscesses at much more remote points, as, for instance, in the brain; and quite recently it has been noted in the pus discharged from the urethra in a case of gonorrhœa. Whether here it played the etiological rôle, one cannot say; but this is rather doubtful, since it is known to be met with in the bladder, prostate, etc.

The *micrococcus tetragenus*, sometimes known as the micrococcus tetragenus septicus, which is frequently, if not invariably, found in the human saliva, and is known to be an occasional pyogenic agent, and belongs, I take it, to the class of obligate rather than of facultative organisms, since if it produce any disturbance at all it is usually in this direction. Abscesses produced by it have a peculiar wide-spread area of induration, and pursue a course so slow as to be very suggestive. Some years ago I reported to this Association a peculiar submaxillary abscess of this kind, and since then have seen similar reports from the experience of others.

The *bacillus pyocyaneus* seems to be an obligate pyogenic organism, suppuration caused by it pursuing almost always a slow and discouraging clinical course. It is an organism apparently quite tenacious of life. My experience in this regard is perhaps peculiar, but may be suggestive. I remember three patients confined successively in one bed in one of my hospital wards, who each pursued a tedious suppurative course, blue pus being the characteristic in each instance, there being no other similar case in the ward during all this time. Whether this was pure coincidence, that three patients with chronic suppurative lesions and with this peculiar organism involved should follow each other in one bed, or whether some germ of the disease lingered in spite of all our precautions, I do not know. The bedding, of course, was so frequently changed as to be beyond suspicion, and the iron beds themselves were as carefully cleansed as could be without burning or firing them.

The Facultative Pyogenic Bacteria.—Study now the organisms—or at least some of them—which have occasional pyogenic properties. And, by the way, whether these latter be due to special activity in the organisms or favoring conditions in the tissues is not yet settled, there being here a most interesting field for research. Probably first upon this list we shall place the *bacillus tuberculosis* of Koch. Although it is well understood that most breaking-down gummata and tubercular lesions suppurate only when we have a secondary or a mixed infection, it nevertheless is, I think, indisputable that the tubercle bacillus may act alone as a pyogenic organism, displaying such properties best perhaps in the case of cranial or spinal meningitis. Here are the locations in which it is most protected from external infection, whereas in the pleura, peritoneum, kidneys, etc., it is difficult to exclude the possibility of mixed infection.

Next to these comes the *tetanus bacillus*, its pyogenic properties being, however, very slight, while its toxic abilities are very great. Nevertheless, it seems probable that even without mixed infection we may have a few drops of pus around an inoculation of tetanus bacilli.

The *bacillus mallei*, or microbe of glanders, should probably be ranged in the same category with the foregoing—most cases of suppurating infectious granulomata due to glanders being, however, examples of mixed infection. The *typhoid bacillus* has not yet been shown to be identical with the colon bacillus, and is capable when inoculated of producing suppuration in animals. Moreover, it is known in rare instances to have the same effect in man.

The *pneumo-bacillus* of Friedländer produces both sepsis and suppuration in some of the lower animals, and is known to produce suppurative bronchial pneumonia and purulent pleurisy in man. Moreover, I have myself once found it in a case of abscess of the shoulder-joint consecutive to pneumonia.

There may also be mentioned the *pseudo-tubercle bacillus* of Malassez and Vignal. This when injected into some animals produces peritonitis and a pseudo-miliary tuberculosis. Other organisms might also be mentioned here—like the *proteus vulgaris*; and perhaps in rare instances the *bacillus of diphtheria* might deserve mention here, although suppuration is not its usual mode of action.

It is not my purpose to catalogue here every organism which has ever been found in an abscess. To do this would impose an almost endless task. Those which I have mentioned above, however, have been met with sufficiently often to justify their position in the above list.

What shall be said of the *gonococcus?* Authorities differ upon this organism. Some claim that by itself alone it is never pyogenic; others that it deserves to be considered as belonging in the above category. My own mind is not yet clear in the matter, since I have never experimented with this organism in pure culture. I do know, however, that I have never found the organism alone in cases of post-gonorrhœal suppuration, and have been led to consider such as either instances of mixed infection or of primary infection not due to the gonococcus but coincident with its existence elsewhere.

Of non-bacterial organisms, of which we have so far made no mention, there are yet a few which call for it. Among the protozoa, for instance, figure the *amœbæ* which produce dysentery and pseudo- or spurious abscesses in the liver. I say "pseudo" or "spurious," because the pus, if such we may call it, from these sources does not seem to be infectious when it escapes into the peritoneal cavity or elsewhere. Here, too, must also be mentioned the various vegetable organisms which are not bacteria—such, for instance, as the *actinomyces*, the *aspergillus fumigatus*, the *leptothrix* of the human mouth, and various other organisms which it is scarcely necessary to mention here.

It is worth while just here to recall for a moment what widely variable action the same organisms may have in different animals. For instance, the microbe of chicken cholera produces among fowl a bloody diarrhœa which is rapidly fatal, while injected underneath the skin of some young quadrupeds it produces only a quantity of pus, in which the organism lives almost indefinitely and preserves its virulence. Again, the glanders bacillus, which produces such well-known symptoms in the horse, in the guinea-pig produces only a normal phlegmon.

Herewith I close a paper too long for comfortable hearing, yet altogether too short for even scant justice to the subject. I beg you to regard it, however, as a plea for more exact teaching concerning matters at one time sadly confused, now much less so, about which students urgently need to be set right at the very outset of their studies. It is never a mistake to be accurate; in surgery it is often fatal not to be.

Garbage Disposal in Southampton, England.—In this city all the garbage is burned in a furnace which was erected at an expense of $18,000, and which consumes from twenty-five to fifty tons of garbage a day at a merely nominal cost.

TWIN PREGNANCY WITH BLIGHTED FŒTUS. ILLUSTRATED WITH A CASE.[1]

By GRACE PECKHAM-MURRAY, M.D.,

MEMBER OF NEW YORK ACADEMY OF MEDICINE, NEW YORK COUNTY MEDICAL SOCIETY, NEW YORK NEUROLOGICAL SOCIETY, ETC.

TWIN pregnancies, according to authorities, occur on an average once in eighty-seven births. It is not so very uncommon, especially in the earlier months, for one of the fœtuses to die or become blighted. The death of the fœtus takes place more frequently at four months than before or after. In 19 cases of Settegast, 8 occurred at four months, 3 at five months, 2 at six months, and 6 at three months. In 29 cases reported by Kieselhausen 11 occurred in the fourth month, and in 23 cases reported by Hohl 13 occurred in the fourth month. In the earlier months it not unfrequently happens that the dead fœtus is cast off, while the other is retained, continues to grow, and is delivered at term. After the second and third months the death of the fœtus does not occasion any trouble, but the pregnancy goes on; the blighted fœtus, called by Stolz an internal abortion, being retained in one of the varying conditions hereafter to be described. An interesting physiological question is, why the pregnancy goes on without an attempt of the uterus to expel the fœtus, when ordinarily it is so prompt to do so. One does not have to go far afield to explain this. It is due no doubt to the fact that the remaining living fœtus gives to the already prepared uterus the necessary impetus to keep up the conditions inaugurated, acting in fact like a single pregnancy. Dr. J. E. Ely suggests that the disease which kills the one fœtus may be insidious, and that the change takes place gradually, and that the lowered vitality of the mother may bring about an inertia of the uterus; but the histories of these cases as a general thing show that the mother is usually well and that she is unaware of anything detrimental having taken place.

In the consideration of twin pregnancies with unequal development of the fœtuses the subject of superfœtation presents itself. It is a moot-point in obstetrical experience and literature. Some deny the possibility of such occurrence, others think that in no other way can certain cases of delayed birth be explained, always excepting those cases in which a bicornate uterus has been demonstrated, of which Klautsch has brought together a number.

In cases of single placenta with double or single sac, there would be no doubt of the pregnancy being a twin pregnancy, having developed from a single ovum with a double germ (Fig. 1). The majority of the cases reported are of this description. In these cases the delivery of one fœtus is followed in a reasonably short time by the delivery of the other. There does not seem to be any rule as to which presents first, the aborted fœtus, or the child that has developed to its natural proportions. Some cases are recorded where both heads have presented simultaneously. If, however, an interval of days, or even a number of weeks, amounting to months, intervenes between the two, it does not seem imperative, as some writers maintain, to call in superfœtation to explain the event. May it not have been that the retained or belated child, having been pressed upon by its fellow and unable to grow, had sufficient vitality to maintain itself until, having the space and nourishment all to itself, it remained *in utero* until a maturer development took place?

FIG. 1.—Case of Papyrus Fœtus. In the larger sac was developed the fœtus born at eight months and died during labor; in the smaller sac was found the flattened fœtus in its appearance representing a child three and one half months old. (Vernier.)[2]

FIG. 2.—Compressed and Macerated Twin Fœtus.

Settegast says that in the first month of a double pregnancy it is possible for one embryo to disappear and leave no trace. From two to six months, if the fœtus dies, it goes through a species of hardening, giving rise to what is termed the mummified or papyrus fœtus, or very rarely it becomes ossified, forming a lithopædion. It remains in one or the other of these conditions, and is so found when the other child is born at term, or at a greater age. Seldom, if ever, is the fœtus found in a state of putrefaction. The contents of the amniotic sac, protected from the air, are prevented from decomposition. Considerable inquiry has been expended to ascertain the cause of this preservation of the dead fœtus, but the matter is very obvious. The air is excluded, and the bacteria cannot enter. Preservative qualities have been attributed to the amniotic fluid. Why the process of mummification should take place is a more intricate problem. Ely says that it occurs three times as frequently in twin as in single pregnancies. There are doubtless in intra-uterine life many chemical processes going on of which we are at present ignorant. It is one of those departments in obstetrics which have not been worked out. Pressure of the growing fœtus is a great factor, no doubt, but is far from accounting entirely for this change in the structure. Absorption of the fluids by the other and living tissues doubtless takes place. A chemical influence has been ascribed to the amniotic fluid, the salts which it contains acting upon the dead mass to harden it. The fœtus whose devel-

[1] Read before the Section of Obstetrics and Gynecology of the New York Academy of Medicine, April 25, 1895.

[2] Nouvelle Arch. d'Obstet. et Gynec., p. 32. 1889.

opment has not been arrested, and whose life has existed up to six months, is simply macerated. Owing to the greater bulk, and the shorter time that life has been extinct, the hardening processes do not go on, and the fœtus is macerated and in most instances compressed, or its development not only arrested but disturbed, resulting in monstrosities.

The causes of the unequal development and death of one fœtus have been much discussed and enveloped in mystery. They are of varying nature, and might in almost every case have been determined, approximately at least, had the investigation of the surrounding circumstances been more carefully carried out. In looking up the literature of these cases one finds a manifest looseness and carelessness in the reports. The causes can be summed up as those occurring, 1, in the mother; 2, in the uterus itself; 3, in placenta, membranes, and cord; 4, in the twins themselves.

1. It would at first appear that if disease or accident should occur to the mother, both fœtuses would suffer. In the few cases reported, in which accident or disease in the mother was brought forward as the cause of the death of one of the twins, the proof that such was the case has been rather shallow. Nevertheless, it is not improbable that trouble in the mother might occasion the death of a fœtus which was weaker and less developed than his brother. Moreover, the demands for growth and nutrition of one having been removed, the other might be the gainer and thus acquire additional strength, and receive a greater impetus, which would enable it to withstand the untoward causes which occasioned the death of the other.

Fig. 3.—Placenta. *A*, Sac, placenta, and cord of healthy child. *B*, Sac, placenta, and cord of dead fœtus.

2. The unequal development of the uterus, or its tardy and insufficient development, might certainly act in a detrimental manner to all or a portion of its contents, and one might perish while the other twin survived.

3. Degeneracy of the placenta, apoplexy of the placenta, placenta velamentosa have been alleged as causes in some instances; insufficiency of development of the portion of the placenta belonging to the blighted twin, as well as partial separation of the placenta from the uterus, limiting the nutrient supply. Few cases have reported microscopical examinations. In many instances the changes which have taken place in the placenta may have occurred after the death of the twin, and have been occasioned by it, rather than occasioning it. However, the troubles with the placenta are no doubt potent factors in many cases. Great changes in the cord have been noted by some writers. The membranes have been thinned, the cord has been short, knotted, strictured, or twisted. There have been stricture of the umbilical vein and stenosis of the navel artery. Another cause of death from the cord is the twisting of it about the neck one or more times. Hupp reports a case where the cord was twisted three times around the neck. He, however, attributes the death of the fœtus to the smallness of the umbilical cord, on account of which the nutrition was insufficient. The death of the other twin, occurring several months later, was attributed to the pyogenic material from its fellow. In estimating the effect of the cord on the death of the child, it should be remembered that many of the changes that take place, as those in the placenta, might occur after the death of the twin, and not have been responsible for it.

4. Conditions in the twins themselves might occasion the death of one or both—anatomical defects, pressure of one fœtus upon the other, and inequality of growth. Peu and Mauriceau are quoted as saying that one fœtus, stronger than the other, takes all the nourishment, and the other perishes by inanition. The power of absorption and assimilation of the one being greater than the other, or, as Professor Eustache poetically expresses it, "they being brotherly rivals," there takes place an intra-uterine struggle for life, which leads to the incomplete development or death of one and the survival and increased growth of the other.

The presentation of these facts in relation to inequality and arrested development of one fœtus, leading to its death by suppression, mummification, compression, ossification, or deformity, has been occasioned by a case in private practice, which led me to investigate and bring together the details of this chapter of obstetrics, interesting more from a physiological stand-point than from its practical bearing, since, almost without exception, it does not complicate either the pregnancy, the delivery, or the subsequent recovery of the patient.

Mrs. T——, primipara, aged thirty-six, began labor March 5, 1894, at two o'clock in the morning, the membranes having ruptured at that time, and the liquor amnii having escaped. With this exception there was nothing abnormal in the labor. The child, which presented in the left anterior occipito iliac position, was delivered at ten o'clock, the placenta following promptly, impressing me only with its great size. It was a female, plump, well formed, and weighed about seven and a half pounds. Upon examining the placenta in it was found a female fœtus (Fig. 2), weighing about a pound and a half, and fourteen and a half inches long. The skull and head were compressed and it was hollowed on one side by the head of the other child, which evidently had fitted into it, as a ball would fit into a cup.

The single placenta was large and full, without any signs of degeneracy (Fig. 3). There were two sacs. The cord of the living child was seventeen inches long, and implanted very nearly in the middle of the placenta. The cord of the dead fœtus was inserted very near the edge and was eleven inches in length. A microscopical examination was made by Dr. Anna W. Williams, who found nothing abnormal either in any portion of the placenta or in the cords.

The case is interesting from two points of view—the advanced age of the fœtus, it being probably very nearly seven months, and the question as to the cause of death. The mother was healthy in every respect, and had met with no accident during her pregnancy. Her recovery was perfectly normal. The death of the child was due either to insufficiency of the placenta, or that portion belonging to it, the cord having been planted too much to one side, or the selfish development of the one child, which crowded the other out, literally driving it to the wall, and crushing its head with its own triumphant growth.

SOME REMARKS ON AMPUTATION AT THE HIP-JOINT, WITH REPORT OF A CASE BY WYETH'S METHOD.

By J. SHELTON HORSLEY, M.D.,

STAUNTON, VA.

The first plan of amputation at the hip-joint, "the most formidable of justifiable surgical procedures," is supposed to have been conceived by Morand, who, with two of his pupils, executed this operation on cadavers in 1738. In 1743 Ravaton devised an operation (practically the same as the modern operations of Lister, Furneaux, Jordan, and others) which he intended performing, but was prevented from doing so by the consulting surgeons.

In 1759 Barbet was awarded a prize by l'Académie Royale de Chirurgie over forty-four competitors for the best essay on hip joint amputations. In this essay he placed on record what is now considered the first hip-joint amputation performed on a living subject. The operation was done by Lacroix, at the Hospital of Orleans, on a boy fourteen years of age, who suffered from gangrene of both lower extremities from eating smutty rye. On the right thigh the gangrenous process had extended higher than on the left, and the line of demarcation had formed at the hip-joint. This limb was almost separated from the trunk by suppuration, when Lacroix completed the separation by dividing with scissors the sciatic nerve and the ligamentum teres. The patient did so well that four days later his left limb was cut off in the upper third of the thigh, which was followed by death in eleven days.

The first successful hip-joint amputation was done in 1772 by Perault, in a case very much like that of Lacroix, in which gangrene following an injury had nearly separated the limb from the body. This surgeon assisted nature by severing the few remaining tissues, and his patient recovered in eighteen months.

The first deliberately planned amputation at the hip-joint through living tissue was done by Mr. Henry Thomson, surgeon to the London Hospital, in 1774. In 1778 Mr. Kerr, of Northampton, also did this operation. Both of these cases were for hip-joint disease, and both resulted fatally. Kerr used an oval incision, the queue terminating externally, and after disarticulating through the outer part of the wound, divided the soft parts on the inner side of the thigh.

Baron Larrey in 1793 was the first to perform a hip-joint amputation in military practice, and from this date to 1809 he did this operation seven times, and one of his cases is supposed to have recovered. This is said to have given it a standing among surgical procedures! The elder Blandin, Larrey's assistant, did the operation three times in 1794 with one recovery. His cases, however, are not very authentic.

The first hip-joint amputation performed in this country was done by Dr. Brashear, at Bardstown, Ky., on a negro, seventeen years of age. He made a circular incision, securing vessels as the operation progressed, then disarticulated by a longitudinal incision on the outer side of the limb. If Blandin's cases of doubtful authenticity be excluded, this is the first successful case on record done through living tissues. In 1812 Brownrigge, a British army surgeon, did the operation successfully.

The three dangers from the operation are hemorrhage, shock, and septicæmia, hemorrhage being the most formidable. The shock is also great. Poppert calls attention to the fact that seventy per cent. of all deaths from hip-joint amputation are from hemorrhage. Therefore, in considering the operation itself, the modes of controlling hemorrhage occupy no unimportant place.

The difficulty in controlling hemorrhage during this operation lies in the facts that the shape of the hip renders the application of an unsupported tourniquet that must be out of the operator's way impossible; that the wound surface is necessarily large, and that the tissues about the hip are very vascular.

The many ways of controlling hemorrhage at the hip-joint may be grouped in four classes:

1. The femoral artery may be ligated or secured before it is divided. This may be done by separate incision, or while fashioning the flaps, as in the external racket incision, or in the transfixion operation of Liston, where it is secured by the assistant's fingers. This is a very old method, having been used by Larrey in 1793, Dr. Brashear in 1806, Sir Astley Cooper in 1824, and later by Roser, Verneuil, and others. Though quite good, it is open to many objections. Ligating the femoral artery in continuity increases the liability to secondary hemorrhage. Securing it does not, of course, interfere with hemorrhage from the branches of the internal iliac artery, which may be quite free.

2. Aortic and abdominal tourniquets, variously shaped, to compress the aorta were used by Pancoast, Lister, Skey, and others. They are very faulty, being only applicable to thin persons, liable to injure the abdominal viscera, and uncertain in controlling hemorrhage.

3. Van Buren, of New York, first suggested compression of the common iliac artery through the rectum, and from this suggestion Davy, of London, devised a lever to be held in place by an assistant during the operation. This is very liable to injure the rectum, and is in the operator's way.

4. The elastic tourniquet, though not perfect, is probably the best method in use. It was employed by Sir Joseph Lister, by Mr. Jordan Loyd, and others. Lister used it to compress the aorta, Loyd to compress the external iliac. Both methods require the use of a special assistant, and are frequently inefficient.

By far the best method now in use is that of retaining the elastic tourniquet in position by the use of skewers. These were used by a number of surgeons, among them Spence, Trendelenburg, Hewson, and Myles. All of these used one steel skewer, to be thrust through the thigh, and a figure-of-eight elastic bandage was carried around it till a flap was made. Then the skewer was removed entirely, or placed in another position, to secure the other flap. Of course, these methods were by no means bloodless, though an improvement.

Trendelenburg's skewer was more complicated than the others. He used in 1876 a steel rod fifteen inches long, one-fourth of an inch wide, and one-eighth of an inch thick, with a movable point attachment. "The rod was pushed through the soft parts, the point removed, and a rubber tube wound round its ends in figure of eight."

It remained, however, for Dr. John S. Wyeth, of New York, to so perfect these methods as to make amputation at the hip-joint practically a bloodless operation. His method is as follows :

"While the member is elevated, or before the Esmarch bandage is removed, the rubber-tubing constriction is applied. The object of this constriction—and it is the chief point in the method—is the absolute occlusion of every vessel at the level of the hip-joint safely above the field of operation." He uses two large skewers or mattress-needles about three-sixteenths of an inch in diameter and ten inches long. One is introduced one inch below and slightly to the inner side of the anterior superior spine of the ilium, "and emerges on a level with and about three inches from the point of entrance" on the outer side of the hip. The second needle is inserted one inch below the level of the crotch, internal to the saphenous opening, and emerges an inch below the tuber ischii. The points of the needles are then shielded with bits of cork to avoid injuring the operator, which Trendelenburg accomplished by a complicated arrangement of a movable point.

The chief and in fact the only objection to this mode of controlling hemorrhage during a hip-joint amputation is the after-oozing. Dr. Wyeth says that this, if excessive, may be completely checked by introducing silkworm gut to be used as secondary sutures, and packing the wound with hot sterilized gauze, which may be removed within forty-eight hours.

As to the methods of operating, which are numerous, Treves gives four classes as covering in principle all these operations :

"1. **Disarticulation Through an External Racket Incision.**"—This is a very popular operation, and in its various modifications has been associated with the names of Ravaton, Malgaigne, Furneaux, Jordan, Lister, Esmarch, and others. Wyeth's method is a modification of this. It consists of a vertical incision from five to seven or more inches long, commencing over the tip of the trochanter major. This is then carried around the inner and back parts of the thigh and joins the end of the vertical incision at the starting-point of the second incision at an obtuse angle. This may be carried out in many ways. Wyeth's method is to make a circular incision through skin and fascia, commencing about six inches below that portion of the tourniquet on the outer part of the thigh. He joins this by a vertical incision from the tourniquet over the trochanter major, and then dissects up the skin to the level of the trochanter minor, where a second circular incision is made to the bone. The attachments of the muscles and the capsular ligament are then divided and the bone disarticulated.

"2. **Disarticulation Through an Anterior Racket Incision.**"—Here the head of the femur is disarticulated through the straight part of the incision, which commences at the middle of Poupart's ligament. This operation is used in conjunction with the first method of controlling hemorrhage, as on account of the nature of the incision no tourniquet can be applied.

"3. **Disarticulation by Antero-posterior Flaps (Transfixion).**"—This method recommended itself to the surgeon before the days of anæsthesia on account of the speed with which it can be executed. It is frequently known as Liston's method. In it the thigh is transfixed by a long knife entering midway between the anterior superior spine of the ilium and the tip of the trochanter major, and is brought out on the inner side of the thigh below the tuber ischii. It is then carried down close to the bone for eight inches, an assistant seizes the femoral artery, and the knife is turned out. The limb is disarticulated and a short posterior flap is cut about on a level with the gluteal fold.

"4. **Guthrie's Operation.**"—In this operation there are antero-posterior flaps of about equal length cut from without in, the incision being begun "a little above the trochanter, carried downward and across the back of the limb, and terminated in front of the tuber ischii. The anterior flap is marked out by a corresponding incision beginning and ending at the same points and crossing the front of the thigh at least five inches below the joint."

As to the relative merits of these operations, the first with its modifications is the best, as the elastic tourniquet can be used with it more successfully. It possesses an advantage over Guthrie's method in not being so readily infected by discharges from the bladder and rectum.

Undoubtedly Wyeth's method, taken as a whole, gives far better results than any other. Ashhurst gives from a table of 633 authentic amputations at the hip-joint a mortality of 64.1 per cent. Wyeth's is 21.4 per cent. from a series of 42 cases by operators of all grades of experience. Davy has a mortality of twenty per cent. out of 10 cases, but, not to mention the serious objection of a limited number, all the cases were operated on by himself. Dr. Wyeth has personally used his method four times, with no mortality. Dr. W. L. Estes reports a mortality of 14.28 per cent. in 7 cases operated on by him after Guthrie's method. He ligated the femoral artery instead of using a tourniquet. The same objections may be urged against his results as against Davy's. Besides, he offers nothing new.

Antisepsis and asepsis would affect Wyeth's mortality rate but very little, as seventy per cent. of the deaths are from hemorrhage and the remaining thirty per cent. is to be divided between shock and septicæmia. So present statistics concerning the mortality of hip-joint amputations can be more justly compared with those of the pre-antiseptic era than in the case of any other operation.

B. F——, aged thirty-six, negro, of Nelson County, Va., was operated on by the writer during August, 1893, and a tumor removed from the inner and lower part of the left thigh, after ligating the femoral artery in Scarpa's triangle. This tumor was very large, being about four and a half inches in diameter. The consultant, Dr. Meeks, and I were uncertain as to diagnosis, as neither of us had examined the patient till a few days before the operation. We were of the opinion that it was a form of aneurism. On its removal the femoral artery was found to be attached to it, and this with the fact that in part of it were many layers of what we supposed was fibrin in some thickness made me believe it an aneurism. A portion of the tumor consisted of small sacs containing bloody fluid. Unfortunately no microscopical examination was made.

Later developments proved, however, that whatever might have been the relation between the tumor and the femoral artery, the growth was evidently malignant in character. About nine months after this operation a small spindle-shaped tumor made its appearance in the upper part of the popliteal space. This grew very rapidly, and soon the thigh was involved and seemed infiltrated, so that by October, 1894, all the thigh except the upper third was involved, and at its largest part measured twenty-six inches in circumference. The pain was very great and the patient was rapidly becoming exhausted. Diagnosis of sarcoma was made and operation decided upon.

On October 17, 1894, I operated, doing Wyeth's hip-joint amputation. I elevated the limb and applied mattress needles and the rubber tourniquet, as above described, without using Esmarch's bandage. The circular incision of skin and fascia was made, then the vertical, the skin dissected up and a second circular made to the bone about opposite the trochanter minor. The attachments of the muscles and the capsular ligament were then divided, and the bone disarticulated, rupturing the ligamentum teres. The vessels were secured and the tourniquet loosened. No more blood was lost than in an amputation through the thigh. The operation lasted about forty-five minutes. Oozing for twenty-four hours was very extensive. The wound was redressed and the drainage-tube removed in thirty-six hours. Most of the wound healed by first intention. A sinus was left, however, by the drainage-tube at the outer portion, which granulated and was not completely healed over till the last of December. When last heard from (April, 1895) the patient was doing well, free from pain, with no signs of the sarcoma recurring.

Microscopical examination of a portion of the involved thigh by Dr. J. S. Davis, of the University of Virginia, proved the growth to be round-celled sarcoma.

MUMPS VERSUS MEASLES; PERIOD OF INCUBATION AND MODIFYING INFLUENCE ONE UPON THE OTHER.

BY BEVERLEY ROBINSON, M.D.,

NEW YORK.

WE do not observe frequently the arresting influence of one contagious and infectious disease upon another. For this reason, as well as because the times of incubation are accurate, the facts which follow are of interest.

A young man, on the thirteenth day of an attack of mumps, walked through the house, but did not see the children subsequently affected. On the nineteenth day of his disease this young man did see the children. A little girl, six years old, developed mumps ten days after possible exposure, and three days after seeing the young man previously attacked with this disease. On the twelfth day, after lunching with a boy affected with measles, the elder sister, thirteen years of age, of the little girl went to bed with high fever and red blotches on her face. The fever remained high during the three following days. At the expiration of this time the eruption of measles was thoroughly developed.

In this instance, on the twenty-second day after exposure to measles, and the twenty-sixth day after exposure to mumps, and the tenth day after the beginning of measles (eruption and fever) the mumps declared itself. The younger child developed measles on the sixth day after the elder girl went to bed with fever, and twenty days after she (the younger child) developed mumps. The latter child had been out of the house for three days, perfectly well—the beginning of this period being seventeen days after the mumps attacked her. The elder girl began to feel badly one week after exposure to measles. The younger girl went to bed with fever six days after actual exposure. Up to that time she felt perfectly well. The day of actual exposure is considered to be the day the elder girl went to bed with fever, although during four days previous she complained of feeling badly. In both cases the probable period of incubation of measles was ten days. The elder girl was exposed to measles when the eruption was already out. The younger girl was exposed probably, as stated, when the elder girl only felt miserable. The incubation period, in each case, therefore, was not affected in duration by the stage of the disease to which there was exposure. With each girl the fever continued very high for three days, and on the fourth day, when the eruption came out thoroughly, it dropped to 99° F. in each case. It had been over 103⅘° F. during forty-eight hours in both cases, and disappeared without apparent influence from medication.

In the case of the younger child there was evidently no influence of mumps over measles, as the former disease had entirely disappeared. In the second case the development of the mumps was obviously held in check by the measles until the twenty-sixth day after actual exposure and the thirty-second day after possible exposure.

The two children whose cases I have reported were in the same room throughout the entire time from the first exposure to the end of the disease.

It should be noted that the attack of mumps in the last case was unaccompanied by fever, and although the jaws were much swollen, there was not great pain in swallowing and no apparent secretion from the parotid glands. At first and just before the rubeolar eruption was manifest in this case, there was high fever, not accounted for satisfactorily by other symptoms present. I thought later that the primary high fever was possibly due to the poison of mumps in the system as much as to that of measles.

In the same house, some weeks previous to the time when the first child developed mumps, there had been two cases of mumps of well-marked severity.

In both these instances there was considerable fever for several days, as well as secretion from the parotid glands. Indeed the discharge from the glands lasted for nearly two weeks. In the case of the first child with mumps there was fever during the first few days, but at no time any secretion from the parotid glands into the buccal cavity.

The Therapeutics of Sydenham.—In the *Glasgow Medical Journal* for April, Dr. Dugald Mitchell discusses "The Therapeutics of Sydenham." That great physician sought above all to impress on his contemporaries the fact that more could be left to Nature than they were in the habit of leaving her. Sydenham insisted that the end would be oftener attained "if Nature were not diverted by ignorant men from the straight way that of herself she holdeth." He was wont to say, "The sick man dies of his physician," thus anticipating an epigram of Lord Byron's. The practical part of Sydenham's mind is well shown in the following passage: "I have ever held that any accession whatever to the art of healing, even though it went no farther than the cutting of corns or the curing of toothache, was of far higher value than all the knowledge of fine points and all the pomp of subtle speculations—matters which are as useful to physicians in driving away diseases as music is to masons in laying bricks."

MEDICAL RECORD:

New York, June 8, 1895.

COLOR-BLINDNESS IN ASIATICS.

DR. F. B. STEPHENSON, surgeon in the United States Navy, has made an interesting contribution to the subject of color-blindness among Asiatics (*Mittheilungen der Deutsche Gesellschaft*, Tokio, 1894).

Collectors of Chinese and Japanese works of art should find his results of especial importance. Dr. Stephenson's researches included Aleuts, Hawaiians, Japanese, Chinese, Siamese, and Koreans. The method employed was usually Holmgren's color-tests, and in many cases only green and red blindness was looked for.

In the Aleutian islands and at Honolulu no examples of color-blindness were found in either sex, but the number tested (37 and 194 respectively) was not large enough to furnish positive proof that these races were free from this abnormality.

In Japan among 1,200 soldiers 1.58 per cent. were red-blind, and 0.833 per cent. green-blind. Among 373 boys, 1 per cent. were red-blind, among 270 girls 0.4 per cent.

Among 887 school-children 5.4 per cent. were myopic. Among 596 men examined by Dr. Berry, of Kyoto, 5.45 showed defective color-sense.

Among the Japanese as a whole, the percentage of color-defect is less than in Europeans or Americans.

Among 796 Chinese examined in various places, no cases of color-blindness were found, but there was a tendency often seen to mix green and blue. This peculiarity was brought out with much greater emphasis by Dr. Adele M. Fielde, of Swatow, China, who examined 1,200 Chinese of both sexes, using Thomson's wool-tests. Among the 600 men were 19 who were color-blind and among 600 women only 1. The percentage of color-blindness among Chinamen is then about 3 per cent. and does not vary greatly from that in Europeans.

Dr. Fielde, however, found that fully half of those tested mixed up blue and green, and this investigator thinks that many of the race are quite blind to violet colors. The Chinese call the sky green, although they have separate names for green and blue and are aware of the distinctions between these colors.

When we consider that at least 200,000,000 of people consider the sky green, it suggests the possibility that after all we in more civilized lands may be mistaken ourselves and that the conception of a blue sky may be one of the results of a deteriorating culture. The Chinese are very fond of colors and adorn themselves with the brightest hues. Their use of and familiarity with them is certainly greater than that of most other races pretending to some civilization, and their skill in manipulating colors artistically in pottery is admitted.

The Asiatics on the whole appear to have less color-blindness and a better sense for color, barring the green and blue, than the Caucasians.

THE PERENNIAL VALUE OF AN OLD DIPLOMA.

THE question as to what becomes of the old diplomas finds a partial answer in the following advertisement, which appeared a short time ago in a Buffalo daily paper.

"FOR SALE.—A physician's diploma from one of the best colleges in the country. Address *Medical News* office."

A valued correspondent wrote to the address given and received a reply which we now have. From this we learn that the advertiser is a graduate of nearly twenty years' standing from a reputable medical college in this State, a physician in regular practice in a small town not far from Buffalo, a member of his county society, and presumably regarded as a respectable member of the community in which he lives. How his neighbors are deceived, if this is the opinion they hold of him, may be learned from his own words. He writes:

"The diploma in question was issued by the Castleton, Vt., Medical College to my father, who died a few years ago, is on sheepskin and is in first-class condition. The name and date you can have changed if you wish, but where a man travels away from home it is only customary to change the date, and that is not always done.

"My price for the diploma is $25.00.

"Of course it is needless for me to say anything about the ease with which money can be made in the practice of medicine if one goes about it rightly. I would advise anyone following the line to travel and advertise, staying from two to three weeks in a place. One can make from $25 to $100 a week. If you should wish to see me personally you can come to —— and return home in a few hours."

And this from a physician, the son of a physician, a member in good standing of the Genesee (N. Y.) County Medical Society! We should advise this man, who respects his father's name as little as he does the honor of his profession, to follow his own counsel and "travel" away from the company of respectable physicians. His letter, which we have in our possession, is at the disposal of the proper authorities who may wish to learn the fate of this particular diploma.

The City Authorities of Louisville, Ky., have assigned one-fifth of the patients of the City Hospital to the charge of the Southwestern Homœopathic College, which is the fifth college in the city.

MOTES AND BEAMS.

The American Humane Education Society boasts that,

"1. It has contributed money to aid the anti-vivisection societies in sending out their literature.

"2. It has now a standing offer of $100 for evidence to enable it to convict any man in medical schools or elsewhere of a violation of the laws of Massachusetts by the infliction of cruelty in performing vivisection on any animal."

With this record as a practical and indiscriminate supporter of anti-vivisection and as a spy upon medical teachers, it sends forth to the medical profession and others a series of questions, and requests replies stating whether (1) the respondent believes in vivisection without restrictions; (2) in vivisection restricted by utility; (3) in vivisection without pain; or, (4) in absolute prohibition of vivisection.

Such an attempt to secure evidence is, on the face of it, farcical. Those who answer will mainly be those who have taken some fanatical interest in the subject, and they will naturally give their vote for anti-vivisection. We expect before long to see some alleged ingenuous statement showing that out of five thousand replies, only five have responded in favor of vivisection! The first instinct of most sensible people in seeing such a document will be to ask why is so much fuss made over vivisection, which hardly exists in this country, when animals are being so constantly tortured by hunters, fishermen, pigeon-shooters, and drivers of dock-tailed horses. Let this alleged Humane Society remove the serious cruelties of sports; stop deer-shooting, pigeon-shooting, fox-hunting; then they can address themselves to the relative trivialities of vivisection.

DR. RUSH AND GENERAL WASHINGTON.

It is, perhaps, fortunate that Congress passed the appropriation for the statue to Dr. Benjamin Rush before the letters of the latter recently published by Mr. Ford in the *Atlantic Monthly* appeared. These letters are full of severe criticisms upon Washington's military and organizing skill, and, according to Mr. Ford, cloak under a pseudo-patriotism a deep personal animus against the Father of our country. Dr. Rush is charged with being at the bottom of the "Conway cabal," which aimed to displace Washington from his command. It is stated, further, that there exists in Philadelphia to-day a biography of Dr. Rush in his own hand-writing, in which frequent comparisons are drawn between himself and Washington, usually to the latter's disadvantage. The publication or sight of this is, however, prohibited. Mr. Ford intimates that Dr. Rush's attitude toward Washington was influenced by small and low motives, and the published letters are asserted to prove this. We believe that the evidence of Rush's whole life should be taken into consideration, however, in judging this matter, and we have no doubt that the memory of Dr. Rush will soon have its defenders.

Dr. Harrison Allen has resigned from the Chair of Anatomy in the University of Pennsylvania.

News of the Week.

Temperance Run Mad.—There is now in Governor Morton's hands, and awaiting his approval or veto, a bill that, should it become a law, will force the pupils in every school under State control, or supported in whole or part by State money, to devote an astoundingly large part of their time to studying the nature and effects of alcoholic liquors, tobacco, opium, hasheesh, chloral, and other baleful sources of reprehensible joys. Four lessons a week on such matters are to be given for at least ten weeks a year in every grade below the second high-school year, and provision is made for excluding from the schools any text-books on hygiene and physiology that do not devote at least a fifth of their pages to instruction of this kind. Regents' and other examinations must include a due proportion of questions about drink and drug evils, and no teacher can be licensed who has not passed a satisfactory examination in regard to his or her knowledge of them. —*New York Times.*

The Committee on Water-supply of the American Public Health Association has issued a call for a convention of bacteriologists of various boards of health to determine upon some system of investigating water-supplies. The meeting is to be held at the New York Academy of Medicine, on June 21st.

The Treatment of the Naval Surgeon.—The injustice done the medical corps of the United States Navy in according to the members inferior rank and pay has long been known as a standing disgrace to the Government, says the *Buffalo Medical and Surgical Journal.* It is only second to that other scandal whereby junior officers are promoted over seniors—a method that deserves the execration of every intelligent American citizen. With a view to correct the former evil, Dr. P. H. Millard, of Minneapolis, introduced the following preamble and resolutions at the late meeting of the American Academy of Medicine in Baltimore, which received the unanimous approval of the Academy:

Whereas, Membership in the medical corps of the navy of the United States from having been, through its high professional attainments, once eagerly sought by graduates of medical colleges, has ceased to be attractive to them, so that it is no longer possible to fill its vacancies; and

Whereas, It is believed that this is due to the inferior rank given to entrants to the corps and their assignment, when at sea, to quarters in the steerage with undergraduates of the Naval Academy and civilian paymaster's clerks, while the young medical officer of the army begins his career a grade higher and in the commissioned officers' mess; and

Whereas, The professional requirements and qualifications, the professional duties and obligations of the medical officers of the army and navy are identical, therefore, be it

Resolved, That the attention of the Senate and House of Representatives of the United States be invited by the American Academy of Medicine to this inequality, and that the naval committees of the two houses be

urged to inaugurate such legislation as shall confer upon the officers of the medical corps of the navy the same status, pay, and emoluments as are now accorded to the medical officers of the army.

Resolved, That this resolution be printed, and copies of it, certified by the President and Secretary of the association, shall be sent to the President of the United States, the Secretary of the Navy, and to every member of the Fifty-fourth Congress.

Similar action was taken by the American Medical Association a day or two later.

Sale of a St. Louis Medical College.—It was generally expected by everybody acquainted with St. Louis college affairs that one or the other of the multitudinous colleges would have to close its doors in the near future. For more than a year it has been rumored that the first college doomed to this fate would be the St. Louis College of Physicians and Surgeons. We have been informed that the board of trustees have at last succeeded in selling the college to Drs. Briggs, Furney, and Morris, who, according to rumor, intend to organize a new faculty.—*Medical Review.*

Another Adirondack Sanitarium.—A new mountain resort for consumptives, named the St. Gabriel's Retreat, will soon be inaugurated under the care of the Sisters of Mercy of Ogdensburg, N. Y. It is to be located at Paul Smith's, in the northern Adirondack region, where a plot of land, one hundred acres in extent, has been secured. A large central hospital with outlying cottages has been planned, in close proximity to pine forests covering thousands of acres. A very large sun-bath portico will be provided. One cottage has been promised by a benevolent lady living at Troy, N. Y.

The Small-pox Epidemic at Hot Springs.—We wish to impress upon the physicians of the country that there is no danger in sending a patient to Hot Springs. The small-pox is over, the editor of this journal was superintendent of the Small-pox Hospital, but was compelled to resign his position for the reason that there were no patients to treat. In all we had 194 cases, with 34 deaths, which is a good showing, especially as we had to contend with a great many syphilitic cases.—*Hot Springs Medical Journal.*

Regulating the Practice of Chiropedy.—The Governor has signed a bill establishing a Board of Examiners in Chiropedy and obliging all practitioners of the art in this State to be examined and registered.

Regulating Veterinary Practice.—The Governor has signed the bill amending the public health law relating to veterinary practice. It provides that hereafter no one shall be admitted to practise veterinary medicine in this State unless licensed and registered by the Regents of the University of the State of New York. A Board of Veterinary Medical Examiners is created. It is to consist of five members, each of whom shall hold office for five years. The State Veterinary Medical Society is to nominate at its annual meetings twice the number of examiners to be appointed that year, and from this list the Regents are to make the appointments. The Regents are given power to remove examiners for misconduct, incapacity, or neglect of duty. It is specifically provided that no person shall practise veterinary medicine "who has ever been convicted of a felony by any court, or whose authority to practise is suspended or revoked by the Regents on recommendation of any State board."

Death of a Physician who Helped to Capture Booth.—Dr. Samuel P. Vonder Smith, one of the oldest and best-known physicians in Essex County, N. J., died May 31st, of consumption, at his home in Bloomfield, aged seventy-four. Dr. Smith became famous from the fact of his being one of the number who captured Wilkes Booth, who assassinated President Lincoln. During the war he enlisted in the Sixth New York Cavalry as surgeon, and later became surgeon of the Sixteenth New York Cavalry. Before the war Dr. Smith was for many years examining surgeon of the New York Police Department, and was at one time examining physician of the Mutual Life Insurance Company of New York. For some time previous to 1872 he had charge of the Indian Department in Arizona. He was in possession of medals awarded for bravery in the war.

Medical Advertisements in the Journal of the American Medical Association.—The American Medical Association has decided that no advertisements of medicinal preparations can hereafter be inserted in the Association journal—after the extirpation of present contracts—unless the exact working formula of the preparation appears in the advertisement.

Association of State Medical Examining Boards.—A permanent national organization of the various State medical examining and licensing boards was effected at Baltimore, on May 9, 1895. Officers were elected for the ensuing year as follows: W. W. Potter, M.D., *President*, Buffalo, N. Y.; J. M. Hayes, M.D., *Vice-President*, Greensboro', N. C.; B. M. Griffith, M.D., *Secretary*, Springfield, Ill. The purposes of the Association are to establish a uniform schedule of requirements for all medical colleges and examining boards, and to assist in perfecting a method for higher medical education.

Sentence of an Illegal Practitioner.—F. W. R. Waring, *alias* Thomas McGahan, was recently sentenced in Yonkers, N. Y., to six months' imprisonment and to pay a fine of $50 for practising medicine illegally. The man was arrested on the complaint of Dr. E. M. Morrell, Secretary of the Westchester County Medical Society. The practice of medicine would appear to have an irresistible attraction for him, for he had already been fined $100 in 1887, and had been sent to Sing Sing in 1889 for the same offence. Quacks who are driven out of New York through the efforts of the New York County Medical Society very often remove to Yonkers and resume their illegal practice there. For this and other reasons it is suggested that a closer union be formed between the New York and the Westchester County Societies, the two oldest county organizations in the State.

The American Laryngological Association will hold its seventeenth annual meeting in Rochester, N. Y., on June 17, 18, and 19, 1895, under the presidency of Dr. John O. Roe.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Tenth Annual Meeting, held at the Army Medical Museum and Library in Washington, D. C., May 30 and 31, 1895.

FIRST DAY, THURSDAY, MAY 30TH.

President's Address.—The meeting was called to order by this address, which was delivered by DR. WILLIAM OSLER. He asked how far had the Association fulfilled the object it had in view at its beginning, and had their aspirations and hopes of 1885 been realized in the advancement of scientific medicine. This was an organization with no code of ethics, no medical politics; no one cares who are the officers and who not. It was not asked from what part of the country a member came, but has he done good work, and still more, if he has anything worth saying and can he say it. Nine volumes of "Transactions" show what has been done. Some of the most noteworthy papers of the past ten years have been brought before this Association, and all the questions of the day had been discussed. The classical work of Fitz and Draper had been brought before them, and in the discussions such subjects as the diagnosis of the diseases of the stomach, of the pancreas, dysentery, infarction, other affections of the bowels, heart disease, sclerosis of the arteries, the mutual relation of renal, arterial, and cardiac changes, anæmia and chlorosis, thrombosis in chlorosis, myxœdema treated with thyroid extract, removal of the ovaries and tubes, subphrenic abscess, acromegaly, and lead-poisoning had all been discussed.

Dr. Osler said: "Our Association has had already a potent influence on the study of pathology and clinical medicine in this country. We need, however, a larger growth of men who are devoting themselves exclusively to these branches. The rapid progress of the medical schools has increased the number of teaching positions in the scientific branches, and there is at present an actual scarcity of thoroughly trained pathologists and bacteriologists to fill them. There is no need to insist upon the necessity of accurate and careful training in the development of workers in these branches. I do not think the profession of this country as yet understands the art of training special clinical physicians, who have taken too much for granted that such men develop readily in the routine of family practice. True, along this path some of the most noted men in our ranks have travelled, but the time has come when able young men should be encouraged to devote themselves to internal medicine as a specialty, content to labor and wait during the first ten or fifteen years of professional life, with pathology as the solid basis of development. Such men will pass to the wards through the laboratories thoroughly equipped to study the many problems of clinical medicine, they will gain the confidence of their professional brethren, and by their accuracy and skill, through them, they will reach the public and a large practice. Such an opportunity and career is within the reach of every physician in any city with a hospital of fifty beds." Dr. Osler then referred to the number of members that had died since the foundation of the Association, and paid a special tribute to the memories of Drs. Alfred Lea Loomis, of New York, and William Cecil Dabney, of the University of Virginia.

Leucomain Poisoning.—This was the subject of a paper by DR. B. K. RACHFORD, of Cincinnati.

DR. F. P. KINNICUTT, of New York, in discussing the paper, asked if he had examined the urine of patients with tetanus. It is very probable that a certain number of cases of tetanus are due to the presence of this substance in the urine. In cases of disordered stomach and severe gastro-intestinal disturbance, the urine might throw some light. He had seen two cases of tetanus, one of which was fatal in twenty-four hours, and at the autopsy the stomach was found to be enormously dilated. The patient had had several previous attacks. In another case, where there was supposed to be cancer present, there was general sepsis, and at the end there was found a gastro-intestinal disturbance.

DR. WILLIAM H. THOMSON, of New York said he was much gratified at hearing this paper. He had long held the view laid down by Dr. Rachford. Many cases of functional neuroses were due more to the action of toxines than to any gastric disease. In many of these forms he has had success with the benzoates of ammonium and sodium. Many of these cases occurred in groups. There were evidences of cumulation, as in uræmia, and the nervous symptom was only seen now and then. In one case which he had there were evidences of heredity.

DR. A. H. SMITH, of New York, asked on what principle he treated these cases with the permanganate of potassium? Was it one of oxidation?

DR. RACHFORD answered that it was one of oxidation, but there were no evidences of it.

DR. FREDERICK C. SHATTUCK, of Boston, asked how long it took to make these tests for xanthin and paraxanthin?

DR. RACHFORD said usually about three weeks.

DR. SHATTUCK asked this because in one case he suspected this kind of leucomain poisoning and the chemist took four weeks to complete his investigation.

DR. J. E. GRAHAM, of Toronto, asked if he had examined the urine shortly before the attacks?

DR. RACHFORD, in conclusion, said he had made examinations of the urine at almost all times, and one week before the attack he failed to find the leucomains. The question of investigation of tetanus had occurred to him, but he had not had a suitable case.

Some Toxicogenic Germs Found in Poisonous Foods was the subject of a joint paper by DRS. VICTOR C. VAUGHAN and GEORGE D. PERKINS, of Ann Arbor, which was read by title by DR. GEORGE DOCK, owing to the absence of the authors.

The Effects of the Gaseous Products of Decomposition upon the Health, and Resistance to Infection of Certain Animals that are Forced to Respire Them.—This was the subject of a paper by DR. A. C. ABBOTT, of Philadelphia, in which he recorded the results of investigations on animals which he subjected to the respiration of vapor vitiated by decomposing substances, sewer air and gas, and other products of decomposition. The animals were put into a bell-jar glass and the air which passed from the outside was forced over the different infusion and decomposing fluids. Last year before this body he had read a paper on the part played by sewer gas or air in causing or disseminating disease. From this paper it was concluded that there was nothing in this air that could be held accountable for causing or spreading disease. In continuing these experiments he presented this paper. Rats and guinea-pigs were confined under bell-glasses, through which was passed continuously, for varying periods, the air from oven substances (meat infusion, sewerage, and urine) in different stages of decay. Some of the animals were subjected to this treatment only, while others were inoculated from time to time during the experiment with cultures of the bacillus of typhoid fever. Of eighteen animals on which the experiments were performed, only two showed any effect; the remaining sixteen presenting nothing that could be attributed to the conditions under which they had lived for from one to five months prior to their being killed. The general condition of these animals during the experiments, as determined by their outward appearance, appetite, and daily fluctuations in weight, was as good as that of other animals kept under the ordinary conditions of the laboratory. In the light of such experiments as are here recorded,

there is but one of two positions to take in regard to the effects of the volatile products of decomposition upon the health and resistance to infection of individuals who respire them, viz., they play no part in either producing diseased conditions or inducing susceptibility to infection, or the indications obtained by such laboratory methods of experimentation as have here been employed are unreliable and not susceptible of general application. We are inclined to accept the former alternative. Ordinarily, in so far as man is concerned, the conditions under which he may find himself may never reach such extremes as those employed in these experiments, as it would hardly seem possible for man to exist under such circumstances. But that he does at times live and perform healthy functions under environments that to most of us would prove highly offensive is an every-day observation among workers in soap factories, glue factories, poudrette establishments, and the like, where the air breathed constantly reeks with the gaseous emanations from putrefying substances. In so far as the sewer gas is concerned, it is, therefore, difficult to conceive that the gaseous emanations from sewers or cess-pools can play a part in the induction of diseases when so highly diluted as they are in the air ordinarily respired by individuals into whose habitations such gases may be admitted.

Renal Affections Following Influenza.—This was the subject of a paper by Dr. C. Baumgarten, of St. Louis. This question is one of great interest. The origin of many cases of nephritis is very obscure. This field is growing narrower by our increased study of its causes. Influenza is one very potent cause, and it is strange that so many authorities are silent on this subject. The literature contains few references to this. It is a more frequent cause of nephritis than the books would have us believe. This complication of the kidney is a frequent, and certainly serious, result of the grip. Besides transient albuminuria, there have been found acute degeneration of the kidney, acute inflammation, both forms of chronic diffuse nephritis, and cases of persistent albuminuria not plainly belonging to one of these groups. He related eight cases. These experiences leave no doubt on his mind that influenza is often the cause of degenerative changes in the kidney. The damage to the kidney does not show itself until the influenza is forgotten. This has been shown in life-insurance-company statistics. During the influenza period and following it he had three and a half per cent. of albuminuria in those examined, and in the non-influenza period he had but one per cent. of cases.

Dr. A. Jacobi, of New York, testified to this complication. He had found it frequently. The diagnosis of this is made easy by the centrifuge. A great many of the cases would have escaped recognition but for this. It is almost impossible with this instrument to miss the diagnosis. The same condition is also found after diphtheria and typhoid fever, and it must be due to the same cause. The toxins of these different diseases give rise to this complication. The microscope should always be used. The periods at which he most frequently found it are between twelve and fourteen and twenty-six. In one of these cases there was alarming hemorrhage; there was albumin, blood, hyaline, granular casts of the thin, fine variety. After all, these cases, contrary to what we find after scarlatina, get well in from two to three weeks or months, and a few become chronic.

Dr. James Tyson, of Philadelphia, said that his observations had been of a different character. He had seen it in persons who had paid him one or two visits, and who had been free from any renal trouble until after an attack of the grip. In other cases of so-called healthy or physiological or cyclic albuminuria he found that after grip this became more serious, and there were casts present.

Dr. Frederick C. Shattuck regretted the absence of Dr. Folsom. Last winter he had seen a number of cases of this kind, and he related a case with nephritis following grip; he had hemorrhages, suppression, and later an enormous amount of albumin. He later became anæmic. Then followed a neuritis, and then death. The autopsy showed gastric complications. Dr. Folsom had reported a case in which there was a large, red, swollen kidney. He thought there was a distinction between the different kinds of kidney complications, for instance after typhoid fever and scarlatina and diphtheria.

Dr. M. H. Fussell, of Philadelphia, had seen two cases which he had not at all suspected, and he thought it showed the importance of examining the urine in all cases in a routine manner.

Dr. A. Jacobi said he wished to correct an impression. He meant the kidney complication not after but during an attack of typhoid fever.

Dr. A. H. Smith, of New York, said this trouble occurred very often, and it is more dangerous in its results than one would suppose.

Dr. Baumgarten, in conclusion, said he was glad to hear his views confirmed by so many competent observers. He always looked for a grip attack when he came across these insidious attacks of renal trouble.

Report on Immunity against Vaccination Conferred upon the Monkey by the Use of the Serum of a Vaccinated Calf and Monkey.—This was a paper by Dr. George M. Sternberg, Surgeon-General, U.S.A., and Dr. Walter Reed, Surgeon, U.S.A. He performed experiments to find out what the effects of blood-serum from a vaccinated calf or from persons with small-pox would have in conferring immunity. The results were rather negative, but there is a short immunity conferred. It takes so much immunized serum to counteract the effect of the vaccine poison that its use is practically impracticable. From one to one hundred to one to fifty is necessary to produce any kind of effect, which would be a very large dose.

Etiology of Idiopathic Hypertrophy of the Heart.—This was a paper by Dr. James T. Whittaker, of Cincinnati. The enlargement is not due to valvular disease or obstruction. The term idiopathic is a misnomer. The cause may be concealed, it may be peripheral, but such terms are too exact. It is not a rare disease. The condition is more frequent than commonly supposed. Many cases are found after a war in a country. The increased size may be noticed by change in the position of the apex. Percussion gives little satisfaction. These hypertrophies may be due to increased resistance in the vascular system, as arterio-sclerosis; to disease of the heart-muscle from infection, degeneration, etc., and to affections of the nervous system. There may be hypertrophy of age, of work, of plethora, of pregnancy, of alcohol, from Bright's disease, from diseases and deformities of the chest, emphysema, kyphosis, myocarditis, syphilis, gout, diabetes, irritation of the vagus, abuse of tobacco, and from excess in venery.

The Transmission of Mitral Diastolic Murmurs.—This was by Dr. J. P. Crozer Griffith, of Philadelphia. He wished to say in advance that all murmurs occurring after the systole and during the diastole were included in this category. The best authorities laid down that the presystolic murmur was heard in a limited area, but he was of the opinion that this murmur was heard far beyond the limits laid down in the books. In giving his opinion he is either saying something that is already well known or he is starting a new point which will bring out discussion. He related several cases and showed plates with the areas marked out, and in some cases the murmur could be heard far beyond its usual limit up into the axilla, but in several it could be heard behind.

Dr. James Tyson, of Philadelphia, said he had seen the first case mentioned and could corroborate what Dr. Griffith said. He related a case himself of a woman, twenty-eight years old, who suffered from lung obstruction, with frothy expectoration. She came to him from

a distance and almost died from the journey. There was an enormous dilatation of the left auricle, as he showed in the specimen. He had recorded a mitral systolic murmur.

Dr. James T. Whittaker, of Cincinnati, said it was not so much the existence of the murmur but its point of greatest intensity. Many extensive lesions give no murmur, and often a loud murmur will amount to nothing.

Dr. Charles Cary, of Buffalo, then made some remarks on direct and indirect murmurs and the explanation on physical grounds and the clinical significance of these murmurs.

Dr. John H. Musser, of Philadelphia, spoke of the work of Dr. Griffith and mentioned a case of his own in comparison. As to what Dr. Whittaker had said, he had seen mitral regurgitations which seemed to be of benefit. In one or more cases the patients had hypertrophy of the heart and many unpleasant symptoms, as headache, nausea, vomiting, and after the regurgitation came the unpleasant symptoms disappeared and the tension was probably relieved. He also spoke of the condition of the valves, and related a case of a sea-captain, fifty-two years old, who had heart trouble from tobacco, evidently a hypertrophy. The man could not believe it was from tobacco, as he had smoked all his life, but he had one or two severe attacks and was frightened into giving up his pipe when he recovered.

Dr. McPhedron, of Montreal, thought that the explanation of most authorities as to the cause of this murmur was incorrect. The loudness of the murmur depended on tension of the blood in the pulmonary circulation.

Dr. A. H. Smith, of New York, thought that murmurs that took place in the diastole were also partly systolic in character. The mitral curtains are stiffened and do not coapt, then there is a regurgitation which reaches a certain point. In many of the presystolic murmurs there is no mitral stenosis at all, and even in health there must be a certain amount of regurgitation.

Dr. Musser repeated what he said, that in hypertrophy after the regurgitation came on the type of the trouble changed and there was often improvement.

Dr. Charles G. Stockton, of Buffalo, asked if it were a diastolic or a presystolic sound. If this is so, then other names hardly apply. If the murmur occurred in the diastole there should be no doubt what it was, and he doubted whether murmurs extended over into the systole, as had been suggested.

Dr. Griffith said, in conclusion, that the position of greatest intensity was in the position of the area of mitral stenosis. There was no murmur over the aortic area or down the sternum. As to the varieties and causes of the loudness he could not say, and he thought that there should be no difficulty in distinguishing the varieties of heart murmurs.

Use of the Differential Stethoscope in the Study of Cardiac Murmurs.—This was the subject of a paper by Dr. A. H. Smith, of New York. In using the ordinary stethoscope there is often loss of time in changing the place of examination, and when there is one murmur at the apex and one at the base it is not always easy to differentiate the time of each exactly. The differential stethoscope enables us to hear separately two sounds produced at the same time in different localities when it is desired to know whether the two murmurs occur alternately or synchronously. The ears may be trained with this differential stethoscope to hear the two sounds separately, just as the eyes may be trained to see separate objects. For this purpose the hearing should be good. There are many conditions very evident in which it might be desirable to use this important aid in diagnosis.

Dr. J. T. Whittaker said this was all very well for those who had perfect hearing in both ears; but, after all, the question of interest was the condition of the heart muscle. This is of prime importance and the differentiation is secondary.

The Cause of the Exaggeration of Sounds Over the Right Upper Chest, both in Health and Disease.—This was a paper by Dr. Charles Cary, of Buffalo. Attention has been called to the unlike physical cause of the disparity in the sounds elicited from the examination of the two sides of the chest. First, is there any difference on the two sides between the sounds elicited by physical examination of the upper portions of the chest in health, or with the same changes in disease? All authorities describe a marked difference as to the percussion sounds, fremitus, respiratory and physical sounds. Louis in 1843 mentioned this, and later Skoda and Flint. There is a relative broncho-vesicular respiration, so natural to the summit of the chest. The right bronchus gives off a branch to supply the upper lobe immediately at but a short distance from the bifurcation of the trachea; this branch is not represented on the left side in man. By pouring a metallic alloy of low fusion into the trachea of a subject, and then eating the tissues off, he obtained a cast of the trachea and bronchi, and this showed his point most clearly. The right bronchus will in most cases intensify the respirations transmitted to the ear or to the hand of the examiner. Few text-books make mention of this. For this reason exaggerated sounds of voice, breathing, percussion, and fremitus, under like conditions, are to be accounted for by this bronchus, which serves as a much more direct transmitting medium. He had made a great many castings from different animals, and in all this condition holds, or its analogy. In answer to Dr. Tyson he said that all branches below this right one were exactly alike in every respect.

Two Cases of Fat Necrosis.—These were reported by Dr. Charles G. Stockton, of Buffalo. Perhaps the most striking feature of the cases under consideration was the existence in both of a well-marked disseminated fat necrosis, and in neither were there well-marked pancreatic changes. There was a complication of the gall-bladder, in the first case in the shape of gall-stones, and in the second case in that of a fibrosis.

(To be continued.)

Bacteriology of Follicular Tonsillitis.—A paper by Dr. Norris Wolfenden on "The Nature of So-called Follicular Tonsillitis and its Relation to Infectious Disorders" describes recent progress in the study of this disease, with special reference to its bacteriology. The author believes that the time is not far distant when we shall classify the inflammatory condition of the tonsils and throat upon a bacteriological and not a clinical basis. He describes briefly four varieties, omitting all cases in which the bacillus of diphtheria plays a part, under the head of staphylococcal, streptococcal, pneumococcal, and Roux and Yersin coccal angina. In all of these forms there may be throat symptoms which resemble diphtheria. "Follicular" tonsillitis is not really follicular at all; it is an acute cryptic infection due to one of these forms of cocci. Its contagiousness appears established in some cases, but is generally not very easily traced. It never appears to attack large masses of people simultaneously, although a number of persons living under the same roof or in similar conditions are frequently affected at the same time, suggesting insanitary surroundings as a common cause. The pathological enlargements of the tonsils, in which a chronic process of catarrh is present in the crypts, form not only the best culture media for a large number of micro-organisms, but give their products an opportunity to invade the system. Clinical appearances alone often allow so little ground for diagnosis of simple tonsillitis from diphtheria that in the absence of bacteriological diagnosis it is wise to isolate such patients from the first. —*The Boston Medical and Surgical Journal.*

AMERICAN GYNECOLOGICAL SOCIETY.

Twentieth Annual Meeting, held in Baltimore, May 28, 29, and 30, 1895.

MATTHEW D. MANN, M.D., OF BUFFALO, PRESIDENT.

FIRST DAY, TUESDAY, MAY 28TH.

(Continued from page 694.)

The Present Treatment of Uterine Displacement.—DR. PAUL F. MUNDÉ, of New York, read a paper on this subject. He was of the opinion that anteflexion produced no symptoms unless there was some downward displacement, and he never used intra-vaginal pessaries for anteflexion alone. One might ask how was it that such acute observers as Dr. Thomas and others had been misled to attribute the relief obtained in anteflexion to the use of pessaries? The answer was, in the light of our present knowledge, that the symptoms were due to such concomitant conditions as inflammations, enlargement of the uterus, etc., and the relief of these by certain of the measures adopted. Dr. Mundé had used supports much more frequently in posterior displacement than in anterior, and yet he did not expect to cure posterior displacement by pessaries. He had not been able to increase his percentage of cures above that mentioned in his paper in 1881, five per cent. He used but one pessary in anteflexion and prolapsus, namely, Gehrung's.

Dr. Mundé had employed Alexander's method of shortening the round ligaments in seventy-seven cases, having been the first to perform it in this country, in 1884, and in a majority the uterus had remained in good condition. He thought that if the ligaments were not found the fault lay with the operator, but it was not the operator's fault if they were thin and broken. He said that he was as much in favor of the operation as ever, although it was attended by certain difficulties, and in some instances the ligaments were liable to break. The second best operative procedure was to shorten the round ligaments within the abdomen. This could be done in the way practised by Mann, Edebohls, or Polk. But he did not approve of opening the abdomen for the purpose alone of shortening the round ligaments, for ventral fixation, nor of operating through the vagina for the same purpose. He had performed ventral fixation about seven times after opening the abdomen for some other purpose, and with good results, but one patient died of heart failure, and another, five months after conceiving, had aborted because the uterus had refused to rise.

The ideal operation for prolapsus had yet to be devised. Plastic operation combined with Alexander's kept the uterus in place for a time, but prolapsus was likely to occur in the event of pregnancy. Where the woman was no longer in a condition to become pregnant he thought the method of the younger Freund, of narrowing the vagina by circular stitches, would prove valuable. He also regarded the procedure of opening the posterior cul-de-sac, freeing the uterine adhesions, and doing Alexander's operation, as one of the recent advancements when employed in suitable cases.

My Experience with Ventro-fixation and Alexander's Operation.—DR. A. LAPTHORNE SMITH, of Montreal, read the paper. He had performed Alexander's operation twenty-one times and ventro-fixation twenty-eight times in the past five years. As he had seen a great many more cases of retroflexion during the same time it showed that he did not think operative interference so frequently called for. The following points with regard to holding the uterus forward were considered in detail: 1, Its effectiveness in accomplishing the object desired; 2, in accomplishing it the smallest possible risk should be attained; 3, in effecting it with the greatest possible ease to the operator. The pessary had many objections: 1, If the ovaries and tubes were bound down it could not be borne; 2, even if there were no inflammation or adhesions, and the uterus and appendages were freely movable, yet the vaginal outlet was generally too large to prevent the pessary from dropping out, and a larger and larger one had to be used; 3, the patient had to come repeatedly to have it renewed; 4, it interfered more or less with sexual intercourse. We must admit, however, that a few cases of retroversion were cured after a few months' use of the instrument. All operators were now agreed that no matter how much one closed the vagina with plastic operations, the uterus would still come down to the vulva. As to removal of the uterus and appendages, it must be remembered that there were other organs which could descend. In comparing ventro-fixation with Alexander's operation, the latter failed in cases where the uterus and appendages were adherent. Indeed, these organs sometimes seemed movable when in fact they were more or less adherent, which would account for some failures with the Alexander operation where they were not expected. Nor was the Alexander operation without risk. A number of patients had come to him in whom it had been followed by a single or double hernia. He had come across two or three cases in which the ligaments had broken on traction, and he had been compelled to finish the operation by opening the abdomen. It should be remembered that in retroversion the round ligaments had not contracted in months or years, and were in a more or less state of fatty degeneration, and hence their liability to give way in Alexander's operation. In doing ventro-fixation the operator was given an opportunity to examine the appendages, break up adhesions, etc., and during the same *séance* he could, if necessary, perform plastic operations on the vaginal walls. The objection that the uterus was a movable organ and should not be put into an immovable position hardly applied to ventro-fixation, for he had found on opening the abdomen a year later that the attachment had become stretched into a pedicle no larger than a lead-pencil, which permitted of sufficiently free movements. An inch or two-inch incision was as a rule sufficiently long. The author preferred to insert two or three silk-worm ligatures, which were left in for one month.

Alexander's Operation.—DR. CLEMENT CLEVELAND, of New York, read the third paper, on "The Treatment of Uterine Displacement." He considered Alexander's operation one of the most beneficent ever devised. One was struck by the not remarkable fact that those who arrayed themselves against it had had no experience, or very little experience, with it, and whose work, for that reason, had probably not been satisfactory. The operation was not an easy one for beginners. Bad results might be said to come from first efforts. He himself had not felt at home with the operation until he had performed it about fifteen times; even now he never felt assured beforehand that he would be able to find the ligaments.

We heard that the operation was dangerous, but statistics spoke differently. There must be two round ligaments, and where they were not found it was the fault of the operator. The fibres might be delicate and fragile, but one who knew how to handle them rarely broke one. They had strength enough to support the uterus to which they were attached. It had been said that shortening them might cause abortion, but he had never seen that accident, nor had he seen the displacement recur after pregnancy. It was his custom, however, to caution his patients, saying that it was unwise to become pregnant within one year after operation, and yet he would not advise abortion. It had also been claimed that invalidism was likely to follow the operation, but such had not been the result. Among all his cases he had seen hernia but twice, and they were among his first cases where the sutures had caused suppuration. If the operation was properly done the uterus was placed in the correct position anatomically, physiologically, and therapeutically. As compared with other operations Dr. Cleveland now

preferred it to ventral fixation, which he had performed many times. Similar objections applied to ventral fixation and antero-abdominal shortening of the round ligaments. The latter, antero-abdominal shortening of the round ligaments, was also likely to fail in case the ligaments had been torn from the pubic spine. In doing Alexander's operation the shorter incision should be used. The ligaments had to be drawn out nearly four inches in nearly every case. Dr. Cleveland then described the details of the operation and his particular method of anchoring the ligaments by using their extremities as sutures. Silkworm-gut was preferred. The same antiseptic precautions were taken as in doing laparotomy.

Dr. Davenport, of Boston, opened the discussion. He thought an operation was necessary only in a minority of the cases of backward displacement of the uterus. Indeed, retroflexion of the uterus was often only temporary in character, and many other women had such displacement for years without any symptom until some special strain or cause gave rise to them. The cases of backward displacement with adhesions did not, of course, come into discussion with Alexander's operation. He must differ with Dr. Smith if the latter preferred ventral fixation to Alexander's operation in simple retroversion. He did not consider Alexander's operation itself perfect. It did not relieve symptoms always, though the uterus was freely movable before operation. The patient frequently continued to complain of pelvic pains and other discomforts. He believed it gave rise to hernia more frequently than was believed, and a strong argument against it was the feeling of numbness and pain at the seat of incision which, in his experience, had not been an infrequent sequel. The round ligaments were not strong enough to retain the uterus in place in certain abnormal conditions of the cervix, of the utero-sacro ligaments, etc., and their own weakness was not the immediate cause of the displacement.

Dr. Ely Van de Warker, of Syracuse, said humorously that since the prevailing surgical spirit both here and abroad might lead to the performance of hysterectomy as the only method of treating retroversion of the uterus, he thought it might be well for some of the old fellows like himself to say something on the other side before it was too late. It had been about twenty years since he had read a paper in which he had brought forward the treatment of flexion of the uterus by the intra-uterine stem, and at no time in the history of the Society had there been an instance in which a young man, or an old one, for that matter, had been so thoroughly sat upon ; but time, of course, brought its own revenge, and one of the gentlemen who then most strongly condemned him had since brought out an edition of his book which fairly bristled with intra-uterine stems.

Dr. Van de Warker thought this instrument, when properly constructed and used in suitable cases, was of great value. Regarding Alexander's operation, he had had a good deal of experience and was not in favor of it. He thought the operation was not scientific. Assuming that it was the function of these ligaments to hold the uterus up, he maintained that the organ had become displaced through some pathological condition, and that it was unscientific to treat the symptom, prolapsus, instead of treating the etiological factor. At any rate there was no proof that the round ligaments held the uterus in the normal position of anteversion. We had to remember that the round ligaments were bands of connective tissue, which underwent enormous elongation and then a certain amount of shortening. By Alexander's operation it was proposed to bring the uterus, which had been retroverted by other causes, into the normal position of anteversion by shortening the round ligaments, and this seemed to him unreasonable. He had done the operation about thirty times, and had not been at all satisfied with the results. One could not tell but what adhesions existed which would make the operation ineffectual unless the uterus was held forward with pessaries.

Dr. H. C. Coe, of New York, thought the last speaker's argument was illogical and founded upon false premises. It was never the intention of the operation to sustain the uterus as a dead weight, nor was that the normal function of the round ligaments. They were not intended to suspend the uterus, but simply to keep it from falling backward, and in shortening them the purpose was not to hold the organ up as a dead weight or to overcome prolapsus. Dr. Coe had observed that the pain present in some cases was due to prolapsus of the ovaries, and lifting these with pessaries gave relief when an operation alone did not. He thought there was no comparison between Alexander's operation and ventro-fixation, as the latter was to be undertaken only after the abdomen had been opened.

Dr. Thomas Addis Emmet, of New York, said it had been his good fortune to see Alexander operate a number of times soon after he had brought the method forward, and had been allowed to introduce his finger into the vagina while the uterus was being drawn forward ; consequently he had come to understand fully the way in which the operation acted, and as a result he had never performed it. The reason was that he believed the cause of the trouble was the degree of prolapsus, not the version. The prolapsus straightened out the vessels, which then became enlarged and engorged. It was the amount of congestion or blood engorgement accompanying the prolapsus which caused the trouble, not the backward displacement. He believed that relief came in the use of pessaries, etc, from lifting the uterus and overcoming the prolapsus, and not in overcoming the retroversion.

Dr. William M. Polk, of New York, said he was sorry to find himself again on the opposite side of the fence from Dr. Emmet. One could not take issue with him on his explanation of the condition which existed, but he could with regard to the actual results of the operation. Alexander's operation had been with us since 1883. It had been performed a great number of times in this country and Europe, and all gave similar testimony to its efficacy in the relief of this condition. In comparing it with ventro-fixation, Dr. Polk said that to limit Alexander's operation to cases in which the uterus and adnexa were freely movable was not necessary, for the reason that recent experience had shown that in other classes of cases it was entirely feasible and safe when preceded by posterior vaginal incision and breaking up of adhesions. Yet ventro-fixation in its proper place was undoubtedly an excellent procedure.

Dr. Baldy, of Philadelphia, dwelt upon the importance of the treatment of inflammatory and other conditions of the uterus complicating retroversion calling for one of the operations under discussion, and also stated in what cases he would resort to hysterectomy.

Dr. George M. Edebohls, of New York, referred to a paper he had read before the Society two years ago relating eleven cases of prolapsus of the uterus and vagina treated by certain plastic operations, and stated that such cases were not extremely rare, and his later experience had confirmed the views then expressed. The statement had been made that when the round ligaments could not be found it was the fault of the operator. He himself had held that view until lately. Two cases had come under his notice in which he was unable to find the round ligaments in their usual position and therefore opened the abdomen. The ligaments were then found from the fundus uteri to the internal ring, but immediately upon emerging from the latter they spread out in a backward and downward direction instead of passing down toward the spine of the pubes.

The author made some closing remarks.

AMERICAN SURGICAL ASSOCIATION.

Annual Meeting, held at the New York Academy of Medicine, New York, May 28, 29, and 30, 1895.

(Continued from page 693.)

Second Day, Wednesday, May 29th.

Treatment of Prostatic Hypertrophy.—Dr. L. S. Pilcher continued the discussion of the subject begun yesterday. He said that since 1893 experience of many surgeons had shown that rapid degeneration and removal of prostatic overgrowth in aged men took place in some cases, and coincident relief to the obstructed flow of urine, after removal of the testicles, but that in certain cases this operation itself precipitated death. It remains, therefore, for the future to accurately determine the relative value and danger of this operation for obstructive prostatic enlargement, as compared with other measures that may be employed. The speaker said he used the term obstructive prostatic enlargement intentionally, for (1) it is only such cases of hypertrophy of the prostate as cause obstruction to the flow of urine that become the subjects of attention, and (2), the enlargement may be caused by widely varying pathological conditions. In the enlargement glandular elements may predominate and adenoma is present; if muscle-fibre, myoma; if fibrous elements, fibroma exists; if epithelial elements prevail, epithelioma is developing. Although muscular, glandular, and fibrous elements do not enter into every case, yet the proportion varies in different ones. Thus the hypertrophy may be in one case dense, partaking of fibroma; or it may be soft, growing rapidly, very vascular, arising from the secreting elements; now the obstruction may be due to accidental swelling, owing to degenerative, congestive, or inflammatory processes.

The relation of castration to these various conditions must be very different. The sudden obstruction due to congestion would not call for castration, nor would malignant and tuberculous enlargement. In cases in which the adenomatous elements prevail analogy suggests, as observed upon the female breast in pregnancy, the close sympathetic relation between this overgrowth of the prostate and the testicles and perhaps account for their shrinkage on their removal. If this be the correct theory then it would follow that it is in the class of prostatic hypertrophies in which the glandular substance predominates that benefit is obtained, and may also explain why in other cases the operation proves useless, as when the enlargement is due to fibrous overgrowth which had in its growth compressed and destroyed much of the normal glandular tissue. As possibly exemplifying this hypothesis the reader narrated a case. Patient was seventy-four years of age, with symptoms of prostatic obstruction for twenty years. There were the usual aggravated symptoms present. Double castration was done on January 19, 1895. At the operation, under anæsthesia, attempts to pass catheters failed. On the sixth day after the operation catheters were passed with ease and thirty-two ounces of urine removed. After this catheterism was easily maintained for the first time for some months. Now he is able to pass spontaneously about one ounce of urine at a time and gradual improvement is taking place. But there has been no apparent diminution in the size of the prostate.

A second case narrated was one of double chronic orchitis in a patient aged sixty-seven. Had had double hydrocele when a young man; neuralgia for fourteen years. Hydrocele cured after tapping. Recent gradual enlargement of the testicles had occurred, each to the size of a hen's egg, not tender, but hard. Under chloroform both testicles were removed. Violent delirium set in as the effects of anæthesia wore off, and continued thereafter. Temperature and pulse rose, respectively, to 102.60° F. and 145 per minute on the sixth day. The amount of urine secreted was normal, but it became albuminous on the fourth day, to twenty-five per cent., with blood and hyaline casts. Primary healing of the wound took place, but the patient died the sixth day from exhaustion.

The speaker said the objections to the operation were principally: 1. Sentimental—not difficult to overcome when once positive assurance of its value can be given; 2. Dangers inherent in the operation are only those of subsequent uræmia. Fauld's cases were referred to, three out of six dying of uræmia shortly after operation, and the case of Buchler.

In the general discussion which followed, Dr. Pierson said that we know too little, as yet, to form just conclusions regarding the value of the operation, but that we ought to make the best use of what we do know, and he thought we had sufficient knowledge to warrant us in undertaking the operation whenever opportunity presented. He had had three cases. One in a man seventy-five years of age, with very aggravated symptoms, including bleeding. After double castration, catheters were left in to drain the urine. There was good progress for six days, when bad symptoms supervened. Opening up of the scrotal wound disclosed gangrene. The patient died on the eleventh day after the operation. The gangrene was probably, he thought, due to infection by the catheter through an unsound urethra. The prostate was found, on post-mortem, to have shrunken. It was a case in which there had been no possibility of mistake in diagnosis.

All his cases were typical hospital ones. Another case of his, with very aggravated symptoms, had been promptly relieved by the operation, the urine, for the first time in several years, being voided without difficulty a few days subsequent to the operation.

Another speaker suggested leaving the wound open sufficiently to allow irrigation, to avoid such complications as in the first case narrated by the previous speaker.

Dr. Alexander, of New York, said that because the operation was so easily performed, he feared it was liable to be entered upon with too little consideration of possible consequences. He said that he was unable to credit the claim that hypertrophied tissue could so quickly degenerate and be absorbed as the cases reported seemed to indicate. The results were more likely due, in many cases, to the skilful services of a competent surgeon in other measures, such as are ordinarily employed, and which are often quickly followed by more or less relief. The cases reported do not altogether satisfy him as to their having been reported entirely without bias. The operation has not yet passed the stage of physiological experimentation, in the speaker's opinion.

Another speaker related a case in which most careful and detailed record was kept by the patient as well as by the surgeons both before and after the operation. The results in this case he would not attempt to explain, but they were too evident not to have impressed him very positively as to the benefits of the operation, in some cases at least. However, since the castration the patient had been subject to sudden flushings and heat and sweating, which he could not account for except as in some way the result of the removal of the testicles. Atropine and other remedies failed to relieve this symptom.

Operative Treatment of Cancer.—Dr. F. H. Garrish, of Portland, Me., opened the discussion in a paper on the "Relation of the Lymphatic System to the Various Regions Most Liable to be Affected by Cancer." The speaker said that he did not imagine that anybody expected him to throw any new light on the subject. Probably the lymphatic system is the least understood of any branch of anatomy; first, because of the imperfect manner of its treatment in textbooks; second, the extreme difficulty of conducting

original investigations. Authors differ greatly, none are probably altogether correct. These faults may arise partly from the actual lack of uniformity of lymphatic distribution. This is probably less regular than that of the veins, notoriously irregular. What is said, therefore, cannot be said dogmatically. The importance of definite knowledge on the subject cannot be exaggerated, as the surgeon who operates for cancer well knows.

Cases have shown that, however early cancer is discovered and removed, involvement of the nearest lymphatic glands had already occurred. It is urgently necessary to know in what direction to look for such involvements, and also, equally, to know where to search for peripheral sources of infection when secondary disease is found in the nodes. The usual relations between each group of those glands which are accessible to operative procedure and the regions from which it derives its supply of lymphatics, the reader demonstrated by drawings on the blackboard. Only about one-fourth of the lymphatic nodes of the body are accessible to operation, and it is improbable that it will ever be regarded as justifiable to attempt removal of any great number of those located in the great cavities. The simple thought of removing the two hundred mesenteric glands, for instance, is appalling. If, then, malignant disease has attacked such region operative measures will not be sanctioned. The reader separated into two groups, by authors compressed in one, a number of nodes. The parotid and internal maxillary, the one situated upon and in the parotid, the other in the side of the pharynx. The lymph vessels from the innermost portions of the breast converge to the internal mammary nodes; a portion of those of the superficial parts of the lateral abdominal walls drift toward the source of the lumbar and ilio-lumbar arteries and end in the lateral lumbar glands; the rectum sends its lymph to the meso-rectal nodes, thence to the sacral, and finally to the lumbar; the uterine absorbents terminate in two sets of glands—from the upper part of the corpus, emptying into the lumbar, accompanied by the ovarian and tubal, those from the lower part of the body and cervix, with upper two-thirds of the vagina, into the internal iliac.

The speaker said that from his drawings, if correct, the efferents of every set of nodes can be determined in an instant, and the glands to which the lymph vessels of any region are tributary can be determined at a glance.

Operative Treatment of Cancer of the Male Genitals.—This paper was by Dr. Hunter McGuire, of Richmond, Va. The speaker said that about one case of cancer of the penis occurred in one hundred cases of cancer, and that the disease usually appears after middle life. Favorite points of attack are the inner surface of the prepuce or glans, more commonly the latter. It begins in a small vesicle or node, which breaks down and leaves an ulcer with dense edges. Irritation causes the ulcer to spread rapidly. The tunica albigenia offers some resistance, but this overcome, the disease spreads to the body of the penis and extends to the lymphatic glands of the groin, shown first near the saphenous opening. Of unoperated cases the average duration is about twenty-two months. The disease is usually epitheliomatous. It demands prompt measures. Syphilis is the only disease likely to be confounded with it. The ulcer covered with dead epithelium and extensive induration will distinguish it usually, if not the microscope will. Phimosis often exists, often causative, and should be split. In early operations prognosis is good, after delay, bad. Very early excision of the ulcer may be sufficient, but the incision should be well outside the indurated base, not leaving an atom of it. If situation preclude the use of the knife, caustics should be employed. Here, too, it is better to remove too much rather than not enough tissue. If extension has progressed too far for simple excision, amputation of the penis should be performed. Of the free portion of the penis this is commonly done by a circular sweep of the knife, severing the member above the point of disease. The urethra is then slit up and sutured to the neighboring skin. The chief objection to this is that the urethra contracts, the urine dribbles, and the cure by granulation is slow. The operation is better done after suitable disinfection of parts contiguous, as follows: The surgeon stands on the right side, a rubber band tied about the penis at the root to control hemorrhage. The knife is passed through the skin at the junction of the corpus spongiosum with corpa cavernosa on one side, brought up the side, over the dorsum and to the corresponding point on the opposite side. This flap should be convex toward the glans, like a flap in leg amputation. Beginning at one end of this flap the knife now transfixes the penis between the corpa cavernosa and corpus spongiosum, coming out at the opposite end of the anterior flap, then carried between them for three-fourths of an inch, then downward and backward to form a posterior flap. This contains the urethra, which should be dissected out of the flap. The corpa cavernosa is now split vertically as far back as the point of transfixion, and the bleeding points are found and tied with fine carbolized silk ligatures with the ends cut close. At least four vessels will require ligatures: the two dorsal arteries and the arteries of the corpa cavernosa. The rubber band is now removed and other bleeding points secured. A small opening is now made in the centre of the anterior skin of flap and the urethra is drawn into this opening, slit up, and stitched in place; at least four (carbolized silk) sutures will be required to make it secure. The anterior and posterior flaps are now joined with sutures of silk or horsehair.

By this operation a covering of skin is secured for the end of the organ, and repair is more rapid than by granulation, which is necessary in the old operation. The urine should be drawn by catheter for several days. A soft catheter should be kept in, unless it causes too much irritation of the bladder or urethra. The stump is dressed with iodoform gauze packed with cotton-wool, and the whole kept in place by proper bandage.

There is tendency to contraction of the orifice of the urethra, and in the four cases which the author has had the patients were instructed to keep it open by passing a short graduated metal sound occasionally. The operation is frequently performed with the galvanic cautery, or by the écraseur, and the urethra treated as suggested by Teale. Those who dread loss of blood are prone to resort to these methods, but primary and secondary hemorrhage have followed both of these operations, and sepsis is more likely to occur than when the knife is used.

It has been urged by some that amputation is not radical enough, but the author believes it is in many cases. The cancer is ordinarily epitheliomatous, like the usual cancer of the uterus and other organs. Of course conditions may indicate more radical procedures. When the disease extends as far back as the scrotum the plan of Mr. Pearce is probably the best to follow.

Medullary cancer of the penis is rare in men, but frequently occurs in boys, spontaneously or from injury. It spreads rapidly. No matter how early and complete the operation it is almost certain to recur.

Cancer of the Scrotum.—Cancer of the scrotum is common in chimney-sweepers, in operatives engaged in manufacturing coal-tar and paraffin. Irritants which penetrate the skin deeply are supposed to be the exciting agency, warts and nodules being first produced, which develop finally into cancer. The type is usually that of large or polymorphous cells. The operation must be a radical one.

Testicle.—Of the testicle, the medullary form is most common, scirrhus rare. Other forms occasionally are seen. The susceptible age is from twenty to forty. It is almost unknown in the very young and rare after

sixty. Contusion is a cause in one-third of the cases, its average duration two years.

Important diagnostic points are: 1. Continual progressing, solid enlargement without inflammation. 2. Unequal consistence in different parts. 3. Absence of transparency. 4. Tendency of scrotal veins to enlarge and scrotal tissue to become adherent. 5. Increasing aches and pain. 6. In doubt, antiseptic tapping or exploratory incisions, preferably the latter. 7. Enlargement of the cord and of the lumbar glands.

Operation—Castration.—*Results:* Danger to life in castration for cancer is slight. Permanent cures are uncertain. Of many reported cases it is unknown whether they were cancer or sarcoma. Curling reports four cases. In twelve cases by Winewater only one escaped recurrence. Kocher reports six cases, all alive after periods varying from one to ten years. In all of these cases microscopical examinations were made. When the disease has progressed so that secondary masses can be felt in the iliac fossa, or lumbar region, or if cachexia is marked, the operation should not be performed.

Cancer of the Prostate.—Cancer of the prostate, although rare, is probably more common than statistics indicate, owing to its being often mistaken for hypertrophy. There are two varieties, the hard and the soft, with very dissimilar clinical courses. The former produces obstruction to flow of urine, desire to void urine, excruciating pain, and presence of blood; while the soft encephaloid variety causes very little early vesical symptoms, but is characterized by rectal pain and tenesmus, and difficulty in defecation. The former variety is the more common; it obstructs and deflects the hard catheter; the soft cancer extends directly backward toward the rectum without affecting the bladder.

Diagnosis is not easy. Severe pain, steady growth of the tumor, characterized by stony hardness in the scirrhous; in the encephaloid, a semielastic fluctuating feel, with rectal hemorrhage, and the cachexia. Microscopical examination of an obtainable fragment, of course, will settle the question. The symptoms which should cause suspicion of hard cancer, as distinguished from prostatic hypertrophy, are: 1. Frequency and difficulty of voiding urine out of proportion to the enlargement. 2. It is often difficult or impossible to pass a steel sound through the warped urethra into the bladder. 3. Continuous pain in the pelvis, often extending to the thighs and legs. 4. Blood often precedes or follows the stream of urine. Prostate enlarged, hard as a stone; the finger in the rectum can often detect induration of one or both vesiculæ seminales.

It is not so easy to distinguish the soft variety. Its presence is usually not suspected until it has progressed very far. The first symptoms are rectal. Frequent urination, tenesmus, blood, and mucus; secondary, frequent micturition, incontinence, and retention. Rectal examination shows a large, soft, elastic tumor, springing from the prostate, pushing backward into the rectum, eventually breaking into it, and filling the pelvis. Treatment consists in alleviating symptoms, unloading the bladder and rectum, etc. The formation of an artificial anus may be required. No radical operation for permanent cure has yet been devised. The prostate and base of the bladder have been removed for cancer of the prostate, but the results are not encouraging.

Eighty or ninety per cent. of cases confirmed by autopsies showed other organs beside the prostate implicated. Any operation to be of value must be early and radical.

Cancer of the Lips, Tongue, Floor of the Mouth, and Pharynx was the title of a paper by Dr. P. S. Conner, of Cincinnati, O. What are the end-results with present methods of operating? what changes, if any, can be advantageously made? the speaker said, were the questions under discussion. Leaving out of consideration other causes of death than the disease itself, in what proportion of cases is recurrence prevented? Wherever situated in the beginning cancer is local. Reappearance after early removal proves imperfect removal.

Cancer of the lip is easily eradicated, while the disease is confined to its free border and to limited infiltration of the underlying tissues, by the V-shaped excision. In the majority of cases this condition does not exist at the time of operation, but the glands under the jaw are implicated. Doubtless at times grandular enlargement is due to irritation, and will subside after the removal of the diseased source, but this is exceptional. Sixty or seventy per cent. of failures to effect cure are due to failure to extirpate affected glands. All enlarged glands should therefore be removed. Thorough exploration for any such should be made. This does not add greatly to the gravity of the operation.

Cancer of the tongue is seen in about one-tenth of all cases of cancer. In a great majority of cases observed glandular enlargement has been present. It affects the glands and the jaw, those along the anterior edge of the sterno-mastoid muscle and those over the carotid sheath, one set or all, according to the situation, age, and other circumstances of the disease. The end-result of operations has been far from satisfactory. Ten per cent. in recent years have died promptly from the operation. Whitehead's death-rate is only 4.5 per cent. Percentage of secondary growths has been from seventy-five to ninety-five per cent. When the tongue has been entirely removed recurrence in the stump has been rare, but occurs in affected glands. Free and early excision, therefore, is very necessary to a cure. It is far better that now and then a syphilitic or tuberculous tongue should be unnecessarily operated on than that cancer should be allowed to extend its area.

The best method of operating is that which permits the readiest and most complete removal of the disease with the least risk of life. Each case has to be operated upon according to its circumstances. When the disease has existed but a short time and located on the free border of the tongue ablation by the knife or scissors should be made. Hemorrhage is slight and healing rapid, the value of the organ but little impaired. When the disease is more extensive, even when so extensive as to require the removal of the whole tongue, Whitehead's operation is a good one. Any operation through the mouth, unless very early and limited, must be supplemented by exploratory incision of the submaxillary region and removal of discovered glands. Even the affected intervening ducts may be left. Very often, if not generally, such intermediate disease exists. Better results will require wider and more thorough explorations than are at present practised. It is through the neck, the floor of the mouth, that we must reach the tongue. Along such routes only is it practicable to arrive at all at the affected tissue.

Primary cancer of the pharynx is rare. Operation for secondary growths in it is for the most part useless, if not injurious. Primary, and confined to the velum, it can be readily removed by knife or scissors. If early and widely done recurrence may not take place. Cancer of the tonsil penetrates the deep tissues so rapidly as to render operations almost wholly useless. Fortunately it is rare.

The session was adjourned until Thursday.

Third Day, Thursday, May 30th.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. L. McLane Tiffany, of Baltimore; *Vice-Presidents*, Christian Fenger, M.D., of Chicago, W. H. Carmalt, M.D., of New Haven; *Secretary*, M. H. Richardson, M.D., of Boston; *Treasurer*, N. P. Danbridge, M.D., of Cincinnati; *Recorder*, De F. Willard, of Philadelphia.

Operative Treatment of Cancer in Various Localities (Continued)—The Breast.—This branch of the subject was treated in a paper by Dr. J. S. Wright, of Brooklyn, N. Y. The speaker, after referring to the subject in some general remarks, described his favorite method of operating and the form of flaps which he preferred, and the process by which he traced lymphatics and explored the axilla for the removal of all possibly infected glands and tissue of every kind. This he regarded, as did all experienced surgeons, as the most important part of the operation, at least the most difficult of performance with satisfaction. Nevertheless, he said, he never occupied more than from thirty to forty-five minutes in performing an operation for removal of cancer of the breast. His method of providing drainage for the wound, referring more particularly to the axillary space, was described.

The reader then gave the history of seventeen unreported cases of cancer of the breast in which he had performed amputation, with a summary of results. One case which was operated upon early, and in which he did not open the axillary region at all, had had no recurrence. Sufficient time had elapsed to warrant the statement that recurrence was safely beyond danger of happening. The reader attributed his excellent results partly to the after-treatment which he invariably employed. This was to administer to the patient, subsequent to the operation, bromide of arsenic for months and even years. He began by giving one-fortieth of a grain a day, and gradually increased the amount to one-fortieth of a grain three times a day.

Operative Treatment of Cancer of the Rectum was the subject of the next paper, which was read by Dr. Arpad G. Gerster, of New York. The speaker began his paper by giving a history of the operation, and describing its gradual development from the time prior to the adoption of antiseptic methods. Even up to 1885 the operation was in a very rudimentary state and very disastrous in its consequences, from uncontrollable hemorrhage and septic infection, etc., so that over half of those operated on died from the effects of the operation. Geunis and Volkman had given an impetus to the attempts at removal of cancer of the rectum by showing that cancer of this organ is less malignant than cancer of glandular structures, such as the female breast, for example. The methods of operation had been limited to the circular incision, the circumanal, perineal, and the coccygeal. The latter operation, involving the removal of the coccyx, was done as early as 1874, and was in the right direction, but its results were not much better than former ones. Volkman accidentally hit upon what proved the key to the solution of the problem, by opening the sacral canal, and finding no bad results to follow. His pupil, Kraské, took up the idea and worked upon it until he devised the operation by removal of a portion of the sacrum, thereby reaching the disease from behind and giving opportunity for drainage and the application of antisepsis, and avoidance of the unavoidable hemorrhage, on account of which all the other operations had been looked upon with so much dread. This operation was published in his remarkable paper on the subject of "Removal of Cancer of the Rectum by Operative Procedures," in 1885. The mortality from the operation was at once reduced from about fifty-five to twenty per cent. A large part of this favorable result was due, however, to the opportunity it afforded for the application of thorough drainage and antiseptic measures. Heretofore this had been impossible to accomplish, but now it became comparatively easy, while also there was opportunity for controlling hemorrhage through the opening in the sacrum, whether at the time of the operation or afterward. Also the operation of removal of the tumor could now be performed under better control and observation, so that there was less danger of causing immediate hemorrhage.

The advantages also were shown in other respects. The gut could now be reached from behind and easily separated from its surroundings and the diseased portion from the healthy portion beyond, and after the removal of the former the stump of the gut disposed of in the way best adapted to the circumstances, or according to the approved method of the operation. In fine, the operation for the first time in its history became easy, safe, and comparatively unbloody, such indeed as the surgeon would be justified in advising and undertaking with some degree of confidence. Doubtless some portion of responsibility for the previous mortality from the operation rested with the lack of preparation to which the gut had been subjected in removal of fæcal matter and thorough antiseptic cleansing. Nothing is more important in connection with the operation than this; and if in order to accomplish it it becomes necessary to perform preliminary colotomy, this should be done. For this purpose the usual site for providing an artificial fæcal exit is in the inguinal region on the left side; but when there is an excessively short meso-colon the operation should be done on the right side. The operation of Kraské remains in its essentials the one at present most approved, but it has been modified and improved upon by several operators, notably Heineké, who makes a T-shaped external incision. This was improved by Koller with a view of dividing the sacrum above. These have been mostly for the purpose of remedying some of the defects of the original and to complete imperfect details. They all are constructed on the same general principles and have the same objects in view for the most part. One operation devised begins with incision at the ilium, which is carried down through the sacrum to the coccyx. In regard to operation for removal of cancer of the rectum in women the author said he regarded it as strange that so direct a road to the goal sought as the vagina provided had been so long neglected. For the first time, he believed, recently an operator (Riens) has successfully removed a cancer of the rectum through this route. He has reported but one case. The speaker said that he did not yet regard the operation as perfected, but that each of the different operations described had some advantages, and each some disadvanges. In regard to position of the patient in operating, he said it was better to have the pelvis well elevated. Besides other advantages, this position tended to diminish hemorrhage. The nutrient vessels of the mesentery must be preserved to nourish the stump of the gut, else sloughing may result. As to dressing, he packs the recesses of the wound with iodoform gauze and applies cotton-wool.

The drawing down of the stump of the gut and sewing it to the external skin was regarded as a great step in advance, when this can be done. There are two objections, chiefly, to the suturing of the stump of the rectum in this way: 1, Frequent failure of primary union; and 2, subsequent stricture. The open plan of treatment of the gut after operation has been found necessary to prevent sepsis. The management of defecation after operation is a serious question, undoubtedly. The author said he did not think that defecation twenty-four hours after the operation was liable to do any harm, but many operators preferred to use opium to prevent movement of the bowels for several days subsequent to the operation.

Dr. McL. Tiffany, in the discussion which now took place on all the papers which had been read under the general subject, spoke of the danger of recurrence after removal by operation of cancer of the breast, in cases in which so long a time had lapsed that it had not been expected—perhaps a year or more. He supposed in such cases that some slight trace of the disease had been left hidden away—in a gland, perhaps—and which had been slow to develop. He had noticed this state of things in several cases of his own, the recurrence showing first along the sternal region. To prevent this happening again he had adopted the prac-

tice, in some cases, of removing the eighth rib so as to get at the lymphatic glands beneath the sternum, which would be found in the periosteum and one in the pleura and pericardium, with the view to examine them and remove any found to be affected.

Regarding operations on the floor of the mouth, it should be done through opening the floor and not through the mouth. The speaker remarked that we are still waiting upon the laboratory for knowledge of the nature of malignant growths. However, his opinion was that the disease is primarily local. Every surgeon, he said, had his pet methods of performing operations and of adjusting flaps, etc., all of which was no doubt of some consequence, but it was inconsequential in comparison, so long as safe plans were followed. The grand object is perfect extirpation of every particle of affected tissue of every kind, wherever situated. His experience taught that a certain number of cases were met with in which, although the disease was completely removed at an early date, recurrence nevertheless took place. It was hard to account for this.

Dr. Theodore A. McGraw, of Detroit, Mich., said that he had determined, in future operations on the tongue and mouth, to dissect for exploration all the neighboring lymphatic regions in relation with the seat of the disease in every case—to go down into the carotid region and explore it thoroughly. For instance, in reference to the case of Dr. Wright, in which there was not recurrence after removal of a cancerous breast without exploration of the axillary region, the speaker said that he had never failed to find evidence, on exploration in this region, of infection, however early the operation had been done. Dr. Wright had simply been very fortunate, but it was not a safe practice to adopt. As for himself, he never neglected to explore the axillary region in operations on the breast.

Dr. Christian Fenger, of Chicago, Ill., exhibited instruments for use in tracheotomy and for plugging the pharynx in operations about the nose and mouth, and described an operation which he performed for cancer of the tongue, by which that organ is removed through the floor of the mouth, demonstrating it by drawings.

Dr. Barnes described dissections of the cheek which he made in exploring for affected lymphatic glands in operating for cancer of the lip. The speaker said that he had taken considerable pains to collect the subsequent histories of his cases, and had succeeded in about forty-five or fifty out of eighty of them. Among these eighty cases two had died from the operation. Of the number whose subsequent histories he had learned, there had been no recurrence in twenty-seven per cent.

Dr. Gerster said, in conclusion, that he was much gratified at the unanimity of expression regarding the great importance of attacking the parts most remotely accessible to infection in removing cancer from any particular region.

The Present State of Anæsthesia.—The first paper on this subject was entitled: "Circumstances under which Chloroform is Preferable to Ether as an Anæsthetic," and was read by Dr. G. W. Gay, of Boston. The speaker said that, in the present state of public opinion regarding the danger of chloroform narcosis, it was perilous to the surgeon to employ it, even if he were convinced in his own mind that it was as safe as ether. If death results from the use of ether, not so very much blame is likely to attach to the surgeon for it; but if he is so unfortunate as to have a patient die under chloroform, he is universally condemned, and it is said that he ought to have known better than to use it. Notwithstanding this sentiment and the risks it entails, over and above medical ones, many surgeons prefer to use chloroform to ether in certain cases and under certain circumstances. The relative danger of the use of chloroform and ether narcosis doubtless varies under different circumstances, and in certain classes of cases chloroform is probably less dangerous to use than ether. The ways in which these agents kill differ from each other. Chloroform kills quickly, ether slowly. Chloroform may prove fatal in the strong and healthy, ether is usually so in the weak and feeble; remedies and measures for resuscitation are, for the most part, useless in chloroform cases, but are frequently available in impending death from ether. Undoubtedly ether is the more safe in general. Deaths, however, which could not have been anticipated are liable to occur with either. Chloroform as an anæsthetic has some advantages over ether, among which are its more rapid action, its more easy administration with fewer unpleasant attendant consequences, such as nausea and vomiting, and its less irritating effects on the respiratory organs. It is largely due to this latter quality that the reader of the paper prefers, he said, to employ it in operations affecting directly, or nearly, the respiratory organs. In tracheotomy for croup or for other conditions requiring it, in which there is any spasmodic condition present, or irritation not of a spasmodic character, chloroform should be employed for narcosis. Ether is irritating to the bronchia, and especially in chronic bronchitis, and chloroform should be preferred to it in patients thus affected. A case of death from suffocation in a child, before it could be brought under the influence of ether narcosis to perform tracheotomy, the reader referred to as illustrating one point of advantage in these cases claimed for chloroform. Had chloroform been used, the operation might have been performed before the child died, because of its quick effect. Suffocation is less liable to result from administering chloroform than ether, and shock is less after chloroform than after ether. In the class of cases described, in which there is disease or irritability of the respiratory organs, ether is often locally very distressing in its use, as well as in its after-effects. Many operations, such as removal of tumors from the larynx, or foreign bodies from it or the trachea, demand an anæsthetic the least irritating to these organs possible. The author said that the only death he had ever had from chloroform narcosis was in an aged and feeble woman. In conclusion, the reader said chloroform is preferable in operations in other regions whenever the respiratory functions are affected, and in all cases of operation upon the respiratory tract.

The Influence of Ether on the Kidneys.—The second paper under the general subject was by Dr. Robert F. Weir, of New York. He first referred to a publication made by himself on the subject in 1890, in which the statistics of forty cases were analyzed, whose kidneys were proved to have been healthy before the administration of the ether, and in which their subsequent condition had been examined into. The result had been to find a trace of albumin after the ether narcosis in twenty-five per cent. of the cases, but of temporary character. Feuter had reported the results of examinations in one hundred and fifty clinical cases and of experiments on thirteen animals, with the conclusions: 1. That ether narcosis produced no perceptible effect on the healthy kidneys in man or in animals. 2. It is not dangerous in health nor when the kidneys are only slightly diseased. 3. Any effects it may produce on the kidneys are very transient.

Since ether has come to be extensively employed as an anæsthetic in England greater opportunities of comparison of its fatality with that of chloroform are afforded than formerly were possible. One investigator has found in ether narcosis, among 350,000 cases, 25 deaths, or a mortality of 1 in every 14,000; while in 134,000 cases of chloroform narcosis there were 46 deaths, or a mortality of 1 in every 3,000 cases. Buller, in 500 cases, after ether narcosis, in persons with previously healthy kidneys, found albumin once. Körté found 5 in 600 cases, under similar circumstances. He asserts very positively that ether does not, but that chloroform does, irritate the kidneys. Garré says that in slight kidney disease ether provokes no important

change, and is very positive in this assertion. Wunderlich gives an exhaustive *résumé* of the subject, and states in conclusion that in existing disease of the kidneys ether frequently augments the disease, but that it is better in this respect than chloroform, two to one, and that casts are found more frequently in the urine as the result of chloroform narcosis than in that of ether. He also says that ether nephritis is capable of being originally excited. Wood does not agree with him altogether. This experimenter, in fifteen animals, found no ether after narcosis in the urine, but did find the epithelium swollen and the kidneys congested. This, according to his view, was caused by some retrograde change in the ether. His conclusions, notwithstanding, are that ether produces no effect in health on the kidneys, but augments disease when previously present. Feuter has demonstrated that the kidneys of animals are much more sensitive to ether than those of man. Bruns has shown that the effects of ether and chloroform on the lungs and kidneys are due to their oxidation and formation of aldehyde and other products of decomposition, caused by exposure of these agents to light and possible admixture with air in partially filled bottles. He advises, in order to prevent these changes taking place, to store them in small, perfectly filled, and hermetically sealed flasks, to be kept in a cool place, impervious to light. These conditions, as we know, are fulfilled by Squibb in this country. He shows that under ether narcosis the temperature falls $\frac{1}{10}^{\circ}$; under chloroform it is unaffected. Ether causes vaso-motor dilatation; chloroform, contraction. According to Fayer and Wright coagulation of albumin in the small vessels and capillaries is induced by imperfect oxidation. This may throw light on the cause of asphyxiation by ether.

Dr. Weir's conclusions were: Of 305 cases collected, there were 254 with normal kidneys before and after ether narcosis; 7 cases with albumin before and after; 3 in which previous albumin was lessened.

Summary: 264 in which there was no bad effect discoverable. There were 31 cases normal before in which albumin was found after ether narcosis; and 8 cases in which previous albumin was increased; 39 cases in all in which perceptible bad effect was produced, or thirteen per cent. of the whole number examined. In the vast majority of cases, therefore, normal kidneys are not affected by etherization. When it does cause albuminuria it is very transient, and does no harm in healthy nor in slightly diseased kidneys. Elevation of temperature, which formerly he thought would augment the work of the kidneys, in connection with ether narcosis, and bring about suppression of secretion, does not appear to exercise much influence in this respect.

In the discussion which followed upon the two preceding papers, Dr. T. F. Prewitt, of St. Louis, said that he had used chloroform largely as an anæsthetic in his practice. He believed that it was preferable as respects safety to ether in patients affected by diseases of the respiratory system, kidney, or brain. He was sure that he had observed bad effects from ether in such cases, but especially in patients with kidney trouble. Suppression of urine, for example, had occurred in some such cases, which he had attributed to the effects of ether. The speaker concluded by saying that in kidney and lung disease he regarded ether as very dangerous.

Dr. H. R. Wharton, of Philadelphia, declared his preference for chloroform in tracheotomy, partly because of its quicker action, thereby consuming less time, which was sometimes the means of saving the life of the patient when the case was very urgent. He had seen a child suffocate in such circumstances, before it could be got under ether anæsthesia. The speaker said that he was in the habit of using chloroform in all cases of children under one year of age, and regarded it as a perfectly safe practice. As to the effects of ether upon the kidneys, he was impressed by considerable experience that it could be safely administered to patients with moderate kidney disease.

Dr. Rushmore said that he had never got rid of the strong impressions of his early medical teachings regarding the danger of chloroform as an anæsthetic, and had, for the most part, refrained from its use. Regarding the advisability of using chloroform in cases affected by lung and laryngeal diseases, it might be pertinent to call attention to the fact that many of these cases were suffering from weak heart, which the safety of the patient demanded should not be aggravated, which chloroform was particularly well adapted to do. A death from chloroform in his practice happened in just such conditions, in a child on whom tracheotomy was about to be performed. The speaker said he desired to emphasize the great importance of the free admixture of air with the ether while the latter was being administered. An open cone should be used, and the ether given regularly and evenly. If this practice were better observed the irritation of the throat and other unpleasant effects, so much complained of, would be much less observed.

Dr. Robert Abbe, of New York, remarked that ether required more skill in administration than chloroform, and that he was hopeful that the time would come when it would no longer be entrusted to the most inexperienced member of the hospital house staff, but only to one who had had experience. He believed that ether left over from an operation should never be used, since exposure to the air, to which it has been subjected, causes it to deteriorate. Properly given, probably one-half the quantity of ether usually given would suffice. Regarding kidney and lung complications, he had come to the conclusion, he said, that those conditions which had been formerly attributed by him to the ether were due largely to sepsis from the wound, or to other causes, and not to the ether. Regarding chloroform for young children, the speaker said, after considerable experience in institutions with them, he had abandoned its use entirely and always gave ether. A fatality from chloroform early in his experience had left a deep impression and deterred him from using it again, while he had the choice of ether. He was sure that local cocaine anæsthesia was being unjustly neglected, and that much more could be done under it than was realized. He had for several years practised its use, and in quite formidable operations sometimes, with perfect satisfaction, doing operations for hernia and laparotomies even. Surely, it might be well used in many cases in which general anæsthesia is for some reason objectionable, and in which, ordinarily, cocaine is not thought of.

Dr. Langé, of New York, said that he had lost patients from ether as well as from chloroform. Death from either may occur where it could not have been anticipated. It is sometimes difficult in a particular case to decide which is preferable. In deciding it is well to bear in mind the public sentiment regarding chloroform and its possible consequences to the operator, should death result from its use. In a case with which he was associated one of the coroner's jury disagreed with the others on the ground that no operator was justified in using chloroform, knowing its dangers, as he should. No doubt, the speaker concluded, the immediate dangers from chloroform are always greater, while the remote ones are greater with ether; it is not possible fully to estimate the actual relation between them in respect to danger.

Influence of Ether Narcosis upon the Genito-urinary Tract was the title of a paper by Dr. John B. Deaver, of Philadelphia. The speaker referred to observations published on one hundred cases, from which it was shown that ether produces perceptible effects on healthy and diseased kidneys. In a large proportion of his own cases investigation showed irritation of the urinary organs in some part. Of forty-seven cases of this kind, in twenty-one the kidneys alone showed it.

The result of his investigations had convinced him, he said, that ether did produce decided effects upon the kidneys, and that it should be given with caution when any disease of these organs existed.

Dislocation of the Ulnar Nerve at the Elbow.—Dr. Henry W. Wharton, of Philadelphia, Pa., read a paper on this subject, in which he gave the histories of one case of his own and of thirteen of other reporters. In his own case the dislocation was the result of trauma in striking the elbow against the stair-case in falling. Trauma was the cause of the dislocation in nearly all the cases. In his case, after reduction of the dislocation by manipulation, a compress was bound on and a splint applied. This was all that was required in this case, but in many, cutting down and stitching the nerve into its groove were required before it could be made to stay there permanently, the tendency being for the dislocation to recur so soon as the dressings are removed. In some of the cases the nerve was injured so as to require resection in order to cure the pain and restore lost function in the peripheral portion. In treating a case, the reporter said, the simpler method of compress and bandage, with splint—which must not be omitted—should always be tried first. This failing, operation by incision and suture of the nerve to surrounding firm tissue in the groove may be resorted to. The symptoms are principally pain and more or less loss of function, sometimes in the parts supplied by the terminal portion of the nerve.

Ligature of the Innominate Artery.—Dr. H. L. Burrell, of Boston, Mass., reported a case and gave a history of the operation, with personal observations. He believed this was the seventeenth case reported. The operation was done for aneurism. The speaker said that probably some of the successful results of the operation reported were due to premature reports. Had he reported his case a little earlier, it would have appeared as a successful case. The first ligature was applied three-fourths of an inch above the aorta. A second was passed about half an inch higher, but was not completed, owing to some symptoms noticed. The patient made a good recovery. Abnormal sensation and local irregularities in the circulation had about disappeared at the eighth day after the operation. The patient left the hospital about the seventieth day from the operation, and went about his business. He appeared to be every way well, but suddenly on the one hundred and twenty-ninth day, he died suddenly, after being seized with faintness and pallor. The complete absence of pain and the perfect comfort of the patient, from the first, following the operation, the speaker said, was quite remarkable.

Immediate Suture of the Gall-ducts and the Gall-bladder after Extraction of Stones, with Cases.—This paper was by Dr. J. W. Elliot, of Boston. The speaker said that during the past year five cases had been operated on by himself, to remove gall-stone from the gall-bladder and duct, and that all the cases had been successful. Two of these cases were read in detail. In the former of these two, a stone the size of a robin's egg was found in the common duct and removed by incision, after which the incision was sutured. No stones were in the bladder. Recovery was complete in three weeks. In the second case the bladder was found to be of immense size. The stones were removed and the bladder sutured. Other attacks came on later and another operation disclosed several stones in the common duct. The case recovered, but with a fistula, which has not yet closed. These five cases, together with cases reported by other operators, prove the safety of the operation, the author said. The ducts should be left as nearly intact as possible. Therefore, the stones found in them should be removed by crushing, if this can be readily done without too much contusion. If not, the duct should be incised and, the stones being removed, sutured. In some cases the wound has been left open and drained with fairly good results; but the incision in the duct should be sutured if possible, as it is in most cases, undoubtedly.

Congenital Œsophageal Pouch; Excision; Immediate Suture of the Œsophagus; Recovery.—This case was related in a paper by Dr. S. J. Mixter, of Boston. In this case the bougie could not at first be passed into the stomach. Finally it did enter the stomach, and it was found that it had formerly been obstructed by passing into a pouch at one side of the œsophagus, about eight inches down. Operation was performed from below, the pouch reached, excised, and the œsophagus sutured at the site of the excision. Prompt recovery took place. It is the only case, the author said, so far as he knew, reported in this country, but several cases have been reported from abroad.

Bacteriological Aspects of Pus and Suppuration was the title of a very interesting paper read by Dr. Roswell Park, of Buffalo, N. Y. (See p. 705.)

In the discussion which followed Dr. Halsted said, regarding pus-production, that the presence of bacterial organisms did not in some instances give rise to the formation of pus, while the same organisms in other cases did give rise to it in large quantities. For example, in gonorrhœal rheumatism the effusion into the joint ordinarily was not purulent, but a few cases have been reported in which pus accumulated in large quantities. According to Dr. Park's nomenclature the swollen joints would not be, properly speaking, inflamed, unless there were virulent pus-producing organisms present in the effusions. But what if they were present and failed to excite pus secretion? It is impossible to know in many cases whether pus is present or absent, except by withdrawal and examination of some of the effused product. As to the pathogenic membrane, which Dr. Park would name pyophylactic, Dr. Halsted said he thought it impossible to explain its cause or purpose satisfactorily. He was not satisfied that Dr. Park's name described a reality any more than the old one.

The speaker referred to experiments made by himself at Johns Hopkins Hospital, concerning the effects of metals on cultures of pus-producing bacteria. It was found that these would not grow in the vicinity of silver, copper, and some other metals. This fact was important in its bearing upon sutures and could be utilized in other directions in surgery. He was now using silver wire as much as possible for sutures, and silver foil for application directly over the sutured wound under the dressing, with the view of preventing suppuration and facilitating primary union, etc.

Dr. Tiffany, in further discussion of Dr. Park's paper, said that he thought that bacteria were present in granulating surfaces, and that the so-called pus secretion was something more than the exuberant repair-material claimed by Dr. Park.

In conclusion, Dr. Park said that as to joints there would not be much difficulty in recognizing when pus was present in the effusion by the symptoms. If there was, examination of aspirated fluid would easily settle it. He regarded it as wrong to go on teaching that everything was inflammation, as had been the custom, and thought himself right in making and teaching his pupils the distinctions formulated in his paper.

A Case of Cholecystotomy was reported in a paper by Dr. S. H. Weeks, of Portland, Me. The case was that of a woman. During about three years she had had most violent attacks, once in every eight or nine months, of excruciating pain, bilious vomiting, convulsions, etc. Latterly, for a year, the attacks had been every two or three months. Among other symptoms were constipation and headache across the forehead, and jaundice.

Diagnosis was made, on admission to the hospital, of cystic calculi. On operation the gall-bladder was found small and containing a dozen small stones. The cystic duct contained one large stone. The duct was

incised and, after removal of the stone, sewed up. Drainage was left in the bladder. There was much pain for some time subsequently, but the patient made perfect recovery.

Hernia of the Bladder as Met with in Operations for Inguinal and Femoral Hernia was the subject of a paper by Dr. Christian Fenger, of Chicago. He described one case in which the patient was obliged to press his hand over an inguinal hernia which existed, in order to empty his bladder. In one case he discovered the condition by cutting into the bladder in operating on the hernia. He referred to thirteen reported cases and read a synopsis of each. The surgeon should be on the watch for the condition, since in several of these (4) the bladder had been cut into with fatal results. The condition may be diagnosed by the appearance of something unusual—a mass which, on tracing up by a sound passed into the bladder and one finger thrust into the abdominal ring, can be correctly diagnosed. This condition occurs in women with femoral hernia. He had observed one such case at his clinic in Chicago.

Injuries to the Pneumogastric.—Dr. Roswell Park, of Buffalo, N. Y., read a short paper on this subject, in response, he said, to an understanding agreed upon with certain members at the last annual meeting, in view of the uncertainty of knowledge accessible on the subject. He had been able to collect from sixty to sixty-five cases of injuries from operations, accidental and intentional. The fatality among these cases was about fifty per cent. He wished especially to call attention to injuries of the phrenic nerve. It had been tied in several instances in ligating the subclavian, and the result had usually been fatal. He said that experiment and observation have shown that paralysis of one-half of the diaphragm puts life in peril. Injury to the phrenic is very serious indeed.

Dr. Bradford, of Boston, displayed photographs of the knees of a man of sixty, who in youth had had suppurative inflammation of one knee-joint, which got well under treatment after a long time, but left what was regarded by his surgeon as irremediable stiffness of the knee. The man was an ingenious Yankee and, disregarding medical advice, rigged up an apparatus consisting of a weight and a rope. The latter was also attached to his ankle, and by long-persistent exercises daily the stiffness was finally overcome and perfect motion restored. He was now sixty years old and this knee as good as the other one. The exhibitor thought the case an instructive one.

The Association was declared adjourned.

AMERICAN MEDICAL ASSOCIATION.

Forty-sixth Annual Meeting, held in Baltimore, May 7, 8, 9, and 10, 1895.

SECTION ON SURGERY.

Third Day, Thursday, May 9th.

(Continued from page 697.)

Asepsis in Private Practice.—Dr. Carl Beck, of New York, claimed that under the present methods of asepsis almost every operation could be done in the patient's room as well as in a hospital. An assistant should be sent the day previous to prepare the room, and nothing should be disturbed for some time before operating.

Ileus was the title of a paper presented by Dr. J. B. Murphy, of Chicago. By the term ileus we mean a complexus of symptoms: abdominal pain of more or less severity, nausea or vomiting or both, and inability to produce a bowel movement. The intestinal canal interests surgeons only from a mechanical stand-point. The causes of obstruction are paralysis of muscles, mechanical obstruction, and spasmodic contraction.

How much of the mesentery can be removed without causing paralysis of the ileus? This depends upon the position of the ligature. The blood is supplied from the mesenteric arteries and also by the parallel artery, which is not accompanied by a vein. In a dog you can cut off the mesenteric supply without producing paralysis, but when both vessels are ligated, you can cut off the supply of only one-half an inch; any more than this will cause a necrosis of the bowel. After the twisting the venous circulation is first disturbed and you get a damming of the bowel; finally you have a cessation of the circulation in the mesenteric vessels, and the last to give way is the parallel vessel. This vessel is protected by a cushion of fat and it takes a long time to effect it. Having no vein to carry back the blood is why we get such a congestion of the bowel. If a thrombus has not been formed the bowel can be passed back into the abdomen. When a section of the intestine is to be removed a little more should be taken from the convex side than from the mesenteric side, otherwise there will be a necrosis of the gut.

Injuries to the afferent nerve will cause paralysis, and he has seen a bowel with a portion of it distended three times its size from this cause. You may have symptoms of ileus from obstruction of the cystic duct, renal calculus, and spasmodic contraction.

The differential diagnosis between local paralysis due to peritonitis and obstruction is very difficult. There may be symptoms of obstruction continuing four or five days without peritonitis, and the presence or absence of peritonitis in early obstruction is a more important point in the diagnosis than any one symptom known.

Scientific Uses of the Surgical Flap was the title of a paper by Dr. George Wiley Broome, of St. Louis, Mo. This paper detailed the influence the proper adjustment of the flap had upon the usefulness of an artificial limb. The particular point of amputation was not the important part of the operation; it was the technique; and if the cicatrix is in the proper place the artificial-limb makers will have no difficulty in supplying a useful article. He regarded drainage-tubes as a source of danger, exposing the wound to the action of one hundred and seventy-eight different species of cutaneous bacteria. A blood-clot in a wound was not a foreign body, while a drainage-tube was.

The Surgical Technique of Aseptic Wounds.—Dr. Henry O. Marcy, of Boston, read a paper with this title, in which he claimed that when suppuration takes place something has been wrong in the technique of the operation or in the after-treatment of the case. Towels wrung out in bichloride solution should be placed around the seat of operation. Frequent sponging of the wound is bad and drainage-tubes are still too frequently used. Sutures of animal tendons are the best, being stronger and lighter than silk, and are not too quickly absorbed. We should not use undue constricting force in buried sutures. A single running suture is best for coaptation of wounds. Aseptic wounds should be closed immediately after the completion of an operation. This abolishes all subsequent danger from frequent dressing and reduces nursing to a minimum.

Pes Planus.—Dr. B. Merrill Ricketts, of Cincinnati, read a paper on "Flat-Foot—Supra-malleolar Osteotomy with Report of a Case—Photographs and Specimens of Feet of Man, Orang, Baboon, Chimpanzee, and Gorilla." He called attention to the fact that children were born flat-footed. Savages wearing no shoes were all flat-footed, as they had little or no arch, and civilization tended to the obliteration of flat-foot. The secret of the arch was civilization. All cases of flat-foot causing pain or discomfort should be subjected to Trendelenburg's operation.

Gall-stones in the Common Duct and their Treatment was the title of a paper by Dr. Christian Fenger, of Chicago. In the majority of cases these are floating

stones, and they sometimes act as a ball-valve. In eighty per cent. of these cases we find, instead of a dilated bladder, a small atrophied one. The symptoms are repeated attacks of pain, but these attacks causing obstruction do not last long enough to cause much jaundice. After repeated short attacks there comes a final attack which kills, and we never know when this final attack will come. In the treatment the usual incision removing all adhesions should be made down to the duct. Sometimes it is impossible to find the stone, as it may slip back into the liver. Out of forty-four operations there has been a mortality of eighteen per cent. Of the writer's three cases all recovered.

Dr. Marcy, of Boston, operated on three cases. In the first case he abandoned the operation, and the patient died ten days afterward. In the second case the duct was opened, and the patient recovered. In the third case the patient died because she was poisoned before the operation.

It was further discussed by Drs. Gaston, of Atlanta, and Weeks, of Maine.

In closing the discussion Dr. Fenger said the incision of the duct should always be closed by a double row of sutures, and drainage invariably carried out.

Skin-grafting after the Method of Thiersch.—This paper was read by Dr. J. C. Oliver, of Cincinnati. This method finds its greatest efficiency in cases where tumors are removed that are so large the flaps cannot be brought together, leaving a large raw surface, replacing cicatricial tissue, and the removal of birth-marks, such as port-wine stains, etc. The operation should be carried out under strictest aseptic principles. Granulations should be scraped away, and if an old ulcer it should be sterilized several days beforehand and all oozing stopped. The grafts should include only the upper layer of skin, and laid on so their edges overlap each other, and covered, so as to keep them in place. Wet or dry dressings can be used. As the hair-bulbs are not included in the grafts, hair will not be transplanted with the grafts. The danger of transplanting disease must always be borne in mind; therefore it is best to get the grafts from the patient's own body.

Complete Dislocation of the Knee of Nine Years' Standing.—Dr. S. F. Forbes, of Toledo, O., reported this case. The dislocation had taken place nine years previous to the operation, and the leg was atrophied and illy developed, and bent at an angle of 45°. After preparing the surfaces of the bones he sutured them with six chromatized catgut sutures with one silver ligature; the periosteum drawn down and sutured with gut and the external flap treated in the usual manner. The leg was then bandaged with strips of wood up as high as the groin. Three weeks afterward the bandage becoming stained from internal discharge, examination revealed that the edge of the upper border of the flap had died and was being cast off. One week afterward the silver wire was lying loose in the bottom of the wound, and it was taken away. From this on the recovery was uneventful, and patient discharged cured ten weeks after the operation with a straight and useful limb, and now walks without crutch or cane.

In excision of the knee-joint direct fixation is unnecessary. External support gives sufficient permanent fixation. Chromatized gut serves two purposes: It keeps the bone steady in the first instance, and keeps the soft tissues from crowding in between the bone surfaces.

Dr. Maclean said Jonathan Hutchinson, of England, condemned this operation, but in his experience he had always obtained good results. He never made use of silver wire, pegs, or other internal methods of fixation. Replying to a question from Dr. Garcelon, of Maine, he said most of his tubercular-joint cases were old ones where the active process had ceased, but he had operated in several cases where the disease was active.

Dr. Davis, of Philadelphia, wished to know if the silver suture which Dr. Forbes had inserted did not have something to do with the good result. He believed the bandage should go up as high as the waist.

Dr. Weeks, of Maine, thought a posterior splint of tin reaching to the ischium was sufficient fixation.

In closing the discussion, Dr. Forbes said with all the muscles cut through at the joint he could not see how there could be any muscular action to disturb the bones, and a bandage to the waist was uncomfortable and unnecessary.

A New Surgical Splinting.—This was an exhibition of the material used by Dr. E. A. Tracey, of Boston, Mass. The splint was made of crushed wood-fibre. While moulding the split the patient should be placed in the proper position and the splint dried over the kitchen fire. Its edges should be covered with chamois and the splint fastened to the limb by roller bandages. Its advantages are strength, extreme lightness, cleanliness, and perfect adaptation to the form of the limb to which it is applied.

A Simple Method of Dressing Fractures of the Extremities.—Dr. John E. Link, of Terre Haute, Ind., described this method, which consisted simply of taking thin shavings of birch-wood, so thin that they could be curled around the finger. These shavings were about four to six inches broad and six to eight inches in length. The roller bandages were moistened and wound around the limb without reversing or twisting, and the shavings placed between the successive layers of bandage at intervals. The advantages were extreme lightness, no heavier than the plain roller bandage, the splints remained exactly where you placed them, and absolute rigidity of the limb.

Dr. Thomas H. Manley, of New York, was pleased to know that plaster-of-Paris bandaging was being driven out, as he thought many of the deformities resulted from the use of plaster. The only objection to the crushed wood-fibre was its expense, which for the present barred it from hospital use. Regarding Dr. Link's material, he thought it the ideal one for fractures in children.

Deformities Following Fractures of the Shafts of Bones was the title of a paper by Dr. Thomas H. Manley, of New York. In adults complicated fractures are succeeded by more or less deformity, regardless of the surgical therapy adopted. The causes of deformity depend chiefly upon two conditions, one preventable in a varying degree and the other beyond our control. In the majority of cases if we use rational methods we secure fair restoration of functions in the normal contour of the limb, but when we have both bones of the forearm completely broken, or the fracture extending into the joint, subluxation or impaction, can we always prevent deformity? His experience with thousands of fractures convinces him that in a considerable proportion of such cases deviations of outline will result.

Hyperostosis with excessive callus follow badly adjusted fractures, which not only impair functions, but may lead to serious pathological conditions by pressure on the main vascular conduits or nerve-roots. Gross distortion generally implies maladroitness or neglect. Among the causes which cannot be removed are, first, those depending on extrinsic circumstances, and, second, those which follow organic or constitutional disturbances. These are pathological. In the treatment of fractures we should always seek to maintain the vitality of the limb and secure osseous repair without disturbing the reposition of the fragments. This is in many cases extremely difficult, especially so in young children and cases badly fed and possibly having atheroma of the arteries.

A rectification of deformities which are not attended with loss of bone or excessive shortening can be accomplished in the early stages. After osseous consolidation is complete, it is a serious question whether rad-

ical surgical interference should be adopted as a routine treatment. As a rule radical interference should be advised only when the functional integrity is seriously impaired or the extent of the deformity is very great.

The usual operations are section of the bone, osteoclasis, osteotomy, and oste-ectomy. The first may be adopted at once, and is of infinite value if done before sclerosis is advanced and the provisional callus resorbed. The other three methods may, under varying circumstances, be very valuable in young healthy subjects: but great care must be taken in their execution upon the shafts of the femur or humerus in adults. In many such cases life itself is imperilled, and in the few in which recovery takes place there is usually permanent anchylosis.

Officers.—The following officers were elected for the ensuing year: *Chairman*, W. C. A. Wheaton, St. Paul, Minn.; *Secretary*, W. L. Estes, of Pennsylvania.

SECTION IN MEDICINE.

Fourth Day, Friday, May 10th.

(Continued from page 701.)

Functional Disorders of the Stomach.—The first paper was read by Dr. J. H. Kellogg, of Battle Creek, Mich., on "New Methods of Precision in the Investigation of Functional Disorders of Digestion." The paper was an illustration of certain modifications made by the writer of the methods of Hayem and Winter of estimating the abnormal acid conditions of the stomach, and was made graphic by the use of colored charts and algebraic symbols. He also exhibited a clinical chart he had devised for a record of the findings in each clinical case. In his system of quantitative determination total acidity is represented by A, and calculated acidity by A′. The acidity and the quantities of chlorine in the different forms of total chlorine (T), free hydrochloric acid (H), combined chlorine (C), and fixed chlorides are expressed as HCl. The values given in his chart relate to 100 c.c. of stomach fluid. The amount of fatty acids, chiefly lactic (L), is expressed in grammes of HCl, which should be multiplied by 2, to determine the actual amount of lactic acid present. The amount of maltose (M) as well as that of soluble starch and dextrine (D) is expressed in grammes of equivalent dextrose. The calculated acidity (A′) is determined by the following formula: C + H − L = A′.

In the study of over four thousand stomach fluids he has found it possible to include all cases of disorder of the chemico-vital processes of the stomach, as regards proteid digestion, in four general classes: Hyperpepsia, hypopepsia, apepsia, and simple dyspepsia (following the classification of Hayem and Winter). Hypopepsia and hyperpepsia present respectively two and three main subdivisions, each of which, together with simple dyspepsia, is divided into two types, according as the measure of the quality of proteid digestion is = or −. Each of these types, together with apepsia, is again subdivided in relation to fermentation into two classes: without fermentation and with fermentation. The characteristics of these several classes, subdivisions, and types are as follows, *x* representing the amount of fatty acids present:

Hyperpepsia.—The characteristic feature in hyperpepsia is A′ +. The significance of this is that the free HCl and combined chlorine (H + C) are found in quantities sufficient to produce normal hyperacidity, there being excess of stomach work, not regarding quality. There are three subdivisions:

1. Hyperpepsia typical, all kinds of work in excess (A′ + H + C +).

2. Hyperpepsia without excess of HCl (A′ + H − or = C +).

3. Hyperpepsia without excess of combined chlorine (A′ + H + C − or =).

Each of the subdivisions of hyperpepsia presents two types:

(1.) *a* =, signifying that the proteid digestion is normal in quality.

(2.) *a* −, signifying that the proteid digestion is inferior in quality, neutral chloro-organic compounds being present.

Each type is subdivided, with reference to fermentation, into two classes:

[1.] Without fermentation (*x* o).

[2.] With fermentation (*x* +).

Hypopepsia.—The charactereristic of hypopepsia is A′ −, the significance of which is that H and C are not found in sufficient quantities to produce a normal degree of acidity. There are two subdivisions of hypopepsia:

1. Hypopepsia typical (A′ − H −).

2. Hypopepsia without deficiency of HCl (A′ − H = or +).

Each of the subdivisions of hypopepsia presents two types:

(1.) *a* =, signifying that the proteid digestion is normal in quality.

(2.) *a* −, indicating the presence of neutral chloro-organic compounds.

Each type is subdivided, with reference to fermentation, into two classes:

[1.] Without fermentation (*x* o).

[2.] With fermentation (*x* +).

Apepsia.—In apepsia there is no normal proteid digestion. The characteristics are a neutral or very slightly acid stomach fluid (A o or −); the coefficient of proteid digestion is zero (*a* o). There are two subclasses in apepsia:

1. Without fermentation (*x* o).

2. With fermentation (*x* +).

Simple Dyspepsia.—The characteristic of simple dyspepsia is A′ =, the significance of which is that H and C are present in sufficient quantities to produce a normal degree of acidity. Simple dyspepsia presents two types:

(1.) *a* =, signifying that the proteid digestion is normal in quality.

(2.) *a* −, signifying that neutral chloro-organic compounds are present.

Each type is subdivided, with reference to fermentation, into two classes:

[1.] Without fermentation (*x* o).

[2.] With fermentation (*x* +).

Some interesting results have come to light in the course of his study of gastric fluids. It was not commonly supposed that much, if any, sugar was present in the stomach during gastric digestion, but he had found from 7 to 8 gm. in 100 c.c. of stomach fluid. Soluble and unconverted starch often accounted for fermentation where there was hyperacidity.

Dr. George W. Webster, in discussing the paper, said that the whole matter of diagnosis of stomach disorders was in considerable confusion. There was a want of knowledge as to what really took place in health. Our first duty was to determine whether any departure had occurred, and if so where and to what extent. All modern physiologists insist upon the importance of salivary digestion, which is not merely a process of short duration in the mouth, but which continues in the stomach for from thirty to sixty minutes in a neutral or even acid reaction, the latter being due to lactic acid. We did not in our therapeutics distinguish between the effects of vegetable and mineral acids. Acetic acid, for instance, may inhibit the salivary digestion in the stomach, and yet in the mouth it will call forth an increased amount of saliva. There was a vital distinction to be made just at this point. Furthermore, greater stress should be laid on the importance of examining the abdomen to determine the size of the stomach, for it was comparatively easy after a little practice to accurately determine by auscultation and percussion the position of its lower border.

Dr. Rochester believed that a little HCl did not interfere with starch digestion.

Dr. Kellogg stated that other vegetable acids than acetic (as in vinegar) were preferable in calling forth salivary secretion. The best method of all was to chew only dry food. Stimulants of all sorts gradually lose their power. He had found that 1 to 4,000 HCl practically stopped salivary digestion.

Suppurative Pancreatitis.—Dr. I. E. Atkinson, of Baltimore, reported a case of suppurative pancreatitis. He was called in December, 1894, to see a woman, the mother of two children, one twelve years and the other six months of age. She was thirty-five years old, with dark eyes and hair, and of stout build, though it was said that she had already lost forty pounds. Fifteen months previously she had had an attack of hepatic colic with secondary jaundice, disappearing after three weeks. No stone was found in the stools. Her pain was constant and then terminated abruptly. She then became pregnant and was delivered in June last. Did not nurse her child. In August she was thrown over the dash-board of a dog-cart and was apparently uninjured, though a slight diarrhœa came on and persisted for awhile after the accident. In September she had another attack of colic with secondary jaundice. The urine was dark-colored and the stools clay-colored. The pain gradually wore away and the jaundice also. Her system became weaker, however, and she was forced to go to bed. Her pains again became frequent, but were milder in character than before. Jaundice reappeared, and she vomited considerable matter, which was at times streaked with blood. Dr. Atkinson first saw her after she had been in bed about two months. Chest examination was negative. She had been vomiting for several days a greenish fluid, but almost without nausea, and had a mild diarrhœa. Singultus had become quite annoying. The spleen was normal, as was also the area of liver dulness. There was some gas in the bowels. In the epigastrium was an indurated area not movable and without fluctuation. Its diameter was three inches in the median line and four and one half inches laterally, extending over to the left mammary line. Percussion over this area gave a relative dulness but no tympanitis. The lower abdomen seemed normal. The urine showed a gravity of 1.020, was acid, and contained a little albumin but no sugar.

Inquiry revealed the fact that she was suffering from severe lancinating pains in the epigastrium, most intense under the xiphoid cartilage, but also felt in the back between the shoulders. The respiration was rapid and almost of a purely costal type. Pulse-rate was also rapid, and there was a slight febrile movement but no chill. Slight sweating about the head only was noted. Symptoms of intestinal obstruction were wanting; in fact there was a tendency to slight looseness of the bowels. The patient lay by preference in a semi-recumbent dorsal position. A diagnosis was made of hepatic colic with impaction of the stone at the mouth of the common duct just where it joins the pancreatic duct, with incomplete obstruction and resulting hyperæmia and inflammation. She continued to fail, and the tumorous area increased downward to the navel level. The diarrhœa continued, but no free fat could be found in the stools. Vomiting continued of greenish fluid mixed with mucus, blood, or recent ingesta. Treatment failed to give any relief and complete anorexia supervened. No operation was deemed justifiable on account of the patient's asthenic condition. Diarrhœa, vomiting, paroxysmal pain (but no fluctuation over the tumor) all persisted. Finally crepitation appeared over the lungs, bloody pus in the stools, with diminution in the size of the tumor, and the patient died in collapse.

At the autopsy only the abdomen could be examined. The belly was tympanitic and on section emitted in an explosive manner a large quantity of foul-smelling pus, but no fluid was found in it. There were multiple peritoneal adhesions, but all easily separated. Areas of fat necrosis were plainly visible in the omentum on the left side over the abscess cavity. The head of the pancreas was obliterated, while the part remaining formed the posterior wall of the abscess cavity, which extended up behind the stomach. The latter seemed to occupy the usual site of the pancreas and lesser omental cavity. A small bit of the pancreas tissue lay loose in the cavity except being attached by a sort of slender pedicle to the adjoining tissues. At the normal site of the mouth of the pancreatic duct there was an opening between the pus cavity and gut, but the origin of the foul gas in the general abdominal cavity could not be learned.

Dr. Atkinson had recently seen another case of pancreas disease, and admitted that this fact enabled him to make an accurate diagnosis earlier than he could otherwise have done, yet he thought that with the classical work of Fitz on this class of maladies in our minds we ought to be able to make a diagnosis in pancreatic disease of the usual type with reasonable promptness. Fitz has divided the disease into three varieties: 1, The hemorrhagic, which often runs its course in a few days. The diagnosis depends on the finding of a tumor, with a somewhat tympanitic note due to the overlying gut, and yet of a poorer tympanitic note than normal intestine. This form might prove fatal if itself or pass into 2, the gangrenous variety, lasting from a few days to six or eight weeks, and resulting fatally from asthenia and sepsis, and 3, the suppurative variety, which might last over a year. As a rule no fat necrosis was present. His own case was undoubtedly originally of the hemorrhagic variety.

Dr. Stockton, in discussing this paper, stated that he had never seen a case of the suppurative variety, though he had seen cases of pancreatitis in which he had failed to make a positive diagnosis. Dr. Atkinson's case showed little depression and shock during its course. The cause of shock here in hemorrhage was probably due to the direct effect upon the sympathetic nervous system. He had never seen fat in the stools in these cases, but had seen it in three cases of malignant disease of the pancreas. In one instance (a girl) he had witnessed shock, vomiting, slight glycosuria, and albuminuria. The pancreas in this case was large and hard like an interstitial kidney. There had been no evidence of hemorrhage or previous trouble of any kind, and the change was not a malignant one. He would like to inquire if Dr. Atkinson had found fat necrosis more common in the interstitial forms of the disease.

In reply, Dr. Atkinson stated that no gall-stones were found on post-mortem examination, and that there had been no fat in the stools. In general he would say that fat necrosis was present except in the acute cases. Glycosuria was by no means common, and when occurring was generally late in appearance. When we opened the abdomen and found fat necrosis, it was of course a beacon-light to suggest at once the nature of the disease.

Methods of Diagnosis and Treatment of the Gastro-intestinal Tract.—Dr. F. B. Turck, of Chicago, read a paper with this title. He spoke of some of the uncertainties of our present methods of examining the stomach and exhibited several pieces of apparatus which he had devised in order to secure more reliable data. The first was the gastric motor meter, consisting of a hollow rubber bag on the end of a tube, which was passed into the stomach in the usual way and the end of the tube then connected with a water barometer. The movements of the stomach compressed the ball, which influence was registered in the fluctuation of the fluid-level in the manometer. This device determined the character and variety of each gastric movement. It also showed the degree of energy exerted on gastric movement by respiration and peristalsis.

The second instrument was called a gyroméle. It consisted of a rotating apparatus to which was fastened

a flexible slender metal arm inclosed in a rubber stomach-tube and ending in a wrapping of soft sponge. The tube and contained arm were passed into the stomach and then by means of the revolving apparatus the brush was made to rapidly revolve inside the viscus. The detection of the "whirring" noise thus made enabled us accurately to determine by auscultation the location and size of the organ. The percussion of hollow viscera gave very uncertain and fallacious results.

Third. He employed a gastric nebulizer and tube. By means of a double tube air charged with oil of cloves and oil of cinnamon was nebulized by one tube into the stomach and passed out by the other tube.

Fourth. A gastric needle douche. A double tube, with one side large but shorter than the other, and ending in a nozzle device, so that by a syringe or elevated reservoir water could be passed into the stomach in the form of a fine needle-spray and would be returned by the other tube as fast as it entered.

He has found that bacterial growth on the walls of the stomach can be greatly checked by the proper use of these various devices. In experiments on animals he makes use of bits of mucous membrane for a natural culture medium for germs removed in the fluid washings. These bits of membrane, after being planted with germ colonies, can be dried and transported as parchment, but upon being remoistened again bacterial growth recommences.

He next considered natural therapeutics in stomach diseases. Lavage was useful, but had been greatly abused. It did not clean off the gastric wall as well as did the needle-spray, and the latter was far more efficacious as a disinfecting process. Massage was also of service. In addition to the nebulization of the oils named, we might use silver nitrate in weak solution, bichloride of mercury, formalin, and other agents. The plan of treatment was antiseptic, prevented the growth of germ colonies, was analgesic, a vaso-motor stimulant, and the rhythmical distention of the stomach with air acted as a sort of pneumatic massage.

As to general therapeutics, he placed much reliance in the use of the warm bath followed by frictions with ice in those cases of stomach disorder attended with great vaso-motor disturbance. Such procedure, however, was contra-indicated in mitral regurgitation and in fatty heart. It also lessened putrefactive changes in the bowel. Here he was accustomed to combine the oils of cinnamon and cloves with ox-gall in a pill enveloped in shellac, in alcohol, and in betol. The usual coverings for intestinal pills, salol and keratin, he had no confidence in. They passed undissolved not only through the stomach but through the bowels also. For food he advocated a liberal use of gems made from bran. The latter acted as a grinding agent, and seemed to assist in the thorough trituration of other foods.

Dr. Stockton remarked, in discussing the paper, that he did not see how brushing the wall of the stomach would help functional anacidity, as marked irritation does not produce acidity in those cases where no lesion of the mucous membrane is apparent. He would agree with the author that there were very decided limitations to the rational use of lavage; on the other hand, he would not go too far in a conservative direction.

Dr. Turck stated in reply that he had found the sponge a better irritant than drugs. By its use he had produced an acidity up to one-tenth of one per cent. HCl. Lavage, if overdone, will not only not help but will actually produce emaciation.

Nuclein and Protonuclein.—Dr. T. O. Sommers, of New York City, read this paper, in which the principal points made were as follows:

1. The first step in the direction of physiological therapy was taken when the leucocyte was found to be a perfect cell with cell-wall, nucleus, and nucleolus. This established it as a vital unit of the organism and referred its origin to the involution of germinal potentiality existing in the original impregnated ovum, and being evoluted through the regular process of segmentation as are all the other elementary tissues of the organism.

2. The second step was taken when the leucocyte was proved identical with the lymph-corpuscle, and even was shown to be the original corpuscle from which the so-called pus-corpuscles were formed under pathological influence.

3. The third step was the proof of the distributing power of the white blood-corpuscles. It is proved that the proteids formed in the digestive tract are all taken up by the leucocyte, many of them, the mononuclear variety, possessing but little blastema and capable of appropriating but little of tissue pabulum. It is in the multinuclear or polynuclear cells that the great change takes place, converting the proteids by mixture with the cell-blastema of the polynuclear leucocyte, under the molecular influence of the nucleus, into the assimilable tissue pabulum which we now recognize as nuclein.

4. When this nucleized pabulum is received by the individual tissue-cell of the several structures of the body, it is then that it passes through that remarkable metabolism or metamorphosis which makes lifeless material again vital and active in physiological function. To this, which is the form of nuclein extracted for therapeutic purposes, the name of protonuclein is given, after the analogy of Professor Huxley's protoplasm which represents the "physical basis of life."

5. This protonuclein is found to be not only a tissue-builder but a direct antitoxic. Indeed, experiments have proved it to be the normal antitoxin of the body, because unless there was some provision made to resist the toxic agents which are introduced every moment into the organism, we would, to use a Pauline expression, "die daily." Its phagocytic action is also clearly shown by the accompanying micro-photographs, taken instantaneously—*i.e.*, in one-half second.

6. The practical demonstration of protonuclein power has been established in hundreds of cases already. Carcinoma, pernicious anæmia, tuberculosis, tonsillitis, cachectic fevers, diphtheria, and other allied disorders of the organism have yielded to its action very promptly, to the great surprise of some of the best clinicians of the land. It has been used with great effect as a tissue-builder in the most typical asthenia and marasmus cases. It is hard, indeed, to limit the therapeutic effect of protonuclein, as will be readily seen by observing the principle upon which its therapeutic effect is based.

7. In the extraction of protonuclein from the lymphoid structures of the body no chemicals are used, nothing but purely physiological methods being applied. The cellular activity is quickly observed with a one-fifth objective by mixing a drop of the blood with supernatant fluid prepared by adding one drachm of water to three grains of protonuclein. Let this stand a few minutes before adding a drop of it to the freshly drawn blood. A most beautiful physiological panorama is exhibited.

8. Protonuclein is prepared in tablets. Powder may also be used as directed hypodermically. It is proved to be a powerful prophylactic as well as a direct antitoxic, the latter effects extending to all zymotic diseases. It will keep indefinitely, being enveloped in benzoin and milk-sugar, preserving its potential activity just as a grain of corn is preserved by its environment.

9. Protonuclein is indicated in any form of disease where the organism is in a low asthenic condition, or in all zymotic or inflammatory conditions, or wherever there are toxic germs to be destroyed.

The following papers were read by title: "The Conservative Use of Lavage in Diseases of the Stomach," by Dr. J. M. G. Carter, of Waukegan, Ill.; "Constipation and Faulty Elimination as a Factor in Disease,"

by Dr. F. S. Thomas, of Council Bluffs, Ia.; "The Physician," by Dr. Julius Kohl, of Belleville, Ill.

Officers.—The following Section officers were elected for the ensuing year: *Chairman*, William E. Quine, of Chicago, Ill.; *Secretary*, De Lancy Rochester, of Buffalo, N. Y.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 1, 1895.

	Cases.	Deaths.
Tuberculosis	54	106
Typhoid fever	7	5
Scarlet fever	101	14
Cerebro-spinal meningitis	3	3
Measles	341	27
Diphtheria	189	40
Small-pox	1	1

The Ungrateful Cough.—Coughs are ungrateful things. You find one out in the cold; you take it up, nurse it, make everything of it, dress it up warm, give it all sorts of balsams, and other food it likes, and carry it around in your bosom as if it were a miniature lap-dog. And by and by, its little bark grows sharp and savage, and—confound the thing!—you find it is a wolf's whelp that you have got there, and he is gnawing in the breast where he has been nestling so long.—*Oliver Wendell Holmes.*

Hepatic Lesions in Typhoid Fever.—Changes in the liver during the course of typhoid fever have been made the subject of study by Dr. Amyot. The conclusions arrived at were based upon the examination of the liver in seven cases. Little nodules were found in all the specimens, in some in small numbers and in others in comparatively great numbers. They varied from about one-fortieth to one-fifteenth of the size of the lobules, and were distributed irregularly. Dr. Amyot divided the nodules into two classes, the lymphoid and the necrotic. Neither of them seemed to be of new growth. At first they appeared to be alike, but afterward became invaded to a greater or lesser extent by lymphoid cells. The nodules were made up of masses of unstained granular protoplasm. In some of these masses the nuclei were still visible, though unstained. Some of the nuclei were broken up into several fragment, which stained diffusely. The capillaries of the nodules were filled with granular material. Lymphoid cells were found chiefly in the capillaries, but a few were seen between the hepatic cells. The so-called lymphoid nodules differed from this only in the difficulty with which the formed elements were seen and on account of the great number of lymphoid cells present. They were sharply cut off from the surrounding tissues. Besides these nodules there were present areas of capillary dilatation, with only the nuclei remaining in the hepatic cells. These areas were of varying size and location, but were generally larger than the nodules before described; they were as a rule circular in form and were not so sharply marked off from the surrounding tissue as the necrotic nodules; they were present in four out of the seven specimens. There was no pigmentation. The other changes in these specimens were nutmeg change, atrophy and pigmentation of the hepatic cells, and dilatation of the capillaries in the intra-lobular vein zone. Fatty degeneration of the cells in the portal vein zone was present in two of the specimens. Beyond some excess of granulation there was no change in the protoplasm of the cells. Dr. Amyot, quoting Dr. Osler, remarks that no definite relation between the typhoid bacilli and the nodules above described has so far been made out.—*Canadian Practitioner.*

An Unpopular but Frequented Health Resort.—The superintendent of the London prison of Pentonville claims that it is the healthiest place in England, there having been but nine deaths among twelve thousand prisoners last year.

The Helmholtz Monument.—Emperor William has promised a gift of $2,500 and a site for the proposed monument to Helmholtz in Berlin, for which contributions are now being solicited in all countries.

Heredity in its Relation to Insanity and Idiocy.—According to Dr. John B. Chapin (*The Cincinnati Lancet-Clinic*), in the procreation of children, if both parents are of exactly equal potency and not related, the expectancy will be that the physical and psychical characteristics of their children will have a close resemblance to the parents. Thirty-one marriages of parties not known to be related or descendants of relations produced two hundred and seven children. None of the children were reported to have been born with any defect (Dr. Bemiss). If the potential power of one parent is less than the other, and this may be the general rule, while the expectancy would be that the offspring would partake of the stronger parent, there is no absolute rule, even here, notwithstanding the probabilities. There is a corrective process in constant operation. That nature, constantly, wholly eliminates or limits the influence of the weaker element is certainly true, as many families show members of very opposite degrees of psychical development. The reverse is also true, that deterioration is sometimes not wholly eradicated, but continues in an increasing degree. Two persons of marked neurotic organization may transmit their temperament to offspring in a more intensified form, and in the second or third generation, if there is no cross by which it may be by chance corrected, a neurotic heredity or predisposition is established, from which may come with slight exciting cause some form of mental degeneration, acute insanity, epilepsy, etc. In-breeding of temperaments, then, rather than consanguineous in-breeding, is more conducive to the development of the neuroses, to eccentricity, and insanity of the general type. In the discussion of heredity in its relation to insanity and idiocy an attempt is made to show the diversity of facts and views that exists, that there is often a personal element which enters in the preparation of statistics, that there are limitations of our knowledge; also, to formulate an expression of views or principles which are now presented as conclusions: 1. Physical characteristics, those distinguishing the human species, are transmissible as an inheritance. 2. Knowledge, genius, and culture are not an inheritance, but depend rather on influence, education, and environment. Mental receptivity is transmissible. Psychical qualities are not necessarily an inheritance requiring favorable surroundings and circumstances for growth and development. 3. Insanity as a disease is not transmissible by inheritance, but may be acquired or evolved from a neurotic heredity as a basis. 4. A neurotic predisposition is transmissible by inheritance, but there is no absolute rule that it will be transmitted in any given case, or in any case. 5. In-breeding of neurotic temperaments is most conducive to the creation of a neurotic heredity. 6. Idiocy and imbecility may be a defect, having an origin in consanguineous marriages, prenatal conditions, accidents, arrested development, infantile meningitis, tuberculosis, and lack of potency on the part of one of the parents from unexplainable causes.

Pneumonia is, according to Osler, a self-limited disease, not influenced by medicine and not cut short by any means at our command.

STRANGULATION OF THE TESTIS AND EPIDIDYMIS FROM TORSION OF THE SPERMATIC CORD.

BY JOHN VAN DER POEL, M.D.,

NEW YORK.

UNTIL within the past few years the subject of strangulation of the testis from torsion of the spermatic cord had received but little attention. Nicoladoni was the first to have reported and described a case of this nature, and although undoubted examples had previously been seen, the cause of the trouble had not been understood; and when the case which I have to report was first seen by me, some twenty months since, I could find but a small amount of literature relating to it, most of this being in the English medical journals, where the cases of Bryant, Whipple, Nash, and Davies-Colley were reported, based upon which my diagnosis was made. As will be seen, my case differs from the others, principally in that the torsion recurred more frequently, and that it was reducible by the patient himself, never having required any further operation than the manipulation of untwisting.

I submit a brief review of each case published up to date, as far as I am aware, that we may be able to note the pathology, causes, and symptoms common to each, with the results obtained in the treatment.

CASE I. (C. Nicoladoni).[1]—A forester's apprentice, sixteen years of age, whose right testicle had never descended. At twelve years he had experienced for the first time an acute pain in the right inguinal canal, and at the same time a small swelling appeared in the region of the external ring, which, together with the pain, disappeared after a few hours' rest. On December 28, 1883, the swelling appeared again, with vomiting and sharp pain on coughing or moving. Three days later he was seen by Nicoladoni in his clinic. He had a painful immobile swelling, the size of a walnut, in the right inguinal canal. Ice was applied, with no result except slight diminution of pain. As the patient feared another attack of periorchitis, he was willing to submit to an extirpation, which was done ten days after admission. In order to lay open the thickened tunica vaginalis both obliquus externus and internus had to be cut, when the sac was found to contain a small amount of bloody, serous fluid, and the bluish-black, pear-shaped, and flattened testicle, whose posterior surface was lightly attached to the sac, and whose cord, two centimetres long, was twisted from right to left—*i.e.*, from without inward, the degree of twist not being stated. The testicle was removed at the internal ring, and a good recovery followed. The cord was completely free, and nowhere held by peritoneal folds. The testis was partly atrophic, and no cause for a primary inflammation could be found, but there was a very evident hemorrhage of the organ, caused by the torsion of the cord, whose veins were completely occluded by the twist, while the lumina of the arteries were still partly patent.

CASE II. (Nicoladoni.)[2]—Day laborer, aged sixty-two, admitted with a swelling of the right scrotal half, which had appeared a few days before, after heavy work, accompanied by pain and vomiting. On account of redness, œdema, and fluctuation, a suppurating periorchitis was suspected, and an incision made. Instead of pus, however, the tunica contained 200 gm. of a hemorrhagic fluid, besides the testis, which was enlarged to one-third beyond its normal size, was of a dark cherry color, and hung on a double pedicle, twisted more than 180°. This case also made a good recovery after extirpation. The testicle was egg-shaped and flattened. Its three-fourths-of-a-centimetre-thick pedicle was composed of the vas deferens, which joined with a second part coming from the rete testis, containing nerves and thrombosed vessels. The enlarged epididymis was the seat of two large cystic growths, which, like the testis, were riddled with small, interstitial hemorrhages. Nicoladoni's general conclusions were that a lately descended testicle, one that was already in the scrotum, was as liable to torsion as one which had been retained in the inguinal canal, presupposing that in both cases the normal fixation was absent, and that it was free and movable on the spermatic cord, or, as he described it, "as a fruit hangs upon its stem." He was the first to draw attention to the condition of hemorrhagic infarction, although I had previously had some forerunners of it in the literature.

CASE III. (the third case[1] is from Helferich's Clinic at Griefswald, reported by Fritz Cahen).—A locksmith, aged twenty-one, who repeatedly from his fourteenth to his nineteenth year had suffered slight attacks of pain in the right testicle, which was still in the inguinal canal. He was admitted with the diagnosis of strangulated hernia, March 8, 1889. Three days before, he had been seized during the night with a sudden sharp pain in the right inguinal region, which he referred to a jump made some days previously. The right testis was not in the scrotum; but on the inner two-thirds of Poupart's ligament there was a tense, elastic tumor, in the upper part of which was a resisting mass. Ice and laxatives for several days did not better his condition. An incision along Poupart's ligament showed a cystic mass as large as a German pipe, continued upward to the internal ring by a thin pedicle. The contents of the sac were a muddy red fluid and the swollen black testis with its cord twisted 360° from without inward. Both cord and testis hung freely within the sac. The testis was removed and the patient made a good recovery in eleven days. The cord was composed of two portions or strands, the larger, the vas deferens and great vessels, the smaller, a number of veins only. Microscopical examination showed all the characteristics of a hemorrhagic infarction of the entire testicle, whose periphery had already undergone a slight necrosis.

CASE IV. (Hans Gervais,[2] from Mikulicz's Clinic at Königsberg).—A boy, aged four years, who six days previously had fallen twelve feet. Two days later there was pain in the belly, below and to the left, and three days after this, swelling and redness of the scrotum, with slight swelling along the cord and inguinal canal of the left side. Examination showed a hard, tender, non-fluctuating tumor in the left scrotal half, adherent to the skin, and from the sensitiveness of the swelling along the canal Mikulicz diagnosed torsion of a lately

[2] Hans Gervais, Inaugural Dissertation, Breslau, January, 1891.

descended testis. On opening the tunica the testis was found of a violet color, the size of a hazel-nut, with a number of dilated veins on the body and head of the epididymis. There was a torsion of 360° at the beginning of the vas deferens, but in which direction it is not stated. This was easily untwisted, and the dark color moderated in a few minutes. Unfortunately an attack of measles intervened on the eighth day, and part of the testicle became necrotic and came away, otherwise recovery was good.

Case V. (Mr. Whipple, reported by W. Gifford Nash.)[1]—A boy, aged seventeen, had had a lump in left groin for seven or eight years, which sometimes disappeared within the abdomen. The day before admission he had strained himself, and felt something give way. Ten hours later he noticed the lump, and had stercoraceous vomiting. Diagnosed as a strangulated hernia, and sent to the hospital. Examination showed an hour-glass swelling, the lower half lying in the scrotum, apparently the testis, while the upper half, the size of a hen's egg, lay on the external ring. No impulse on coughing. Operation disclosed a tense, dark-colored sac, containing blood-stained fluid and a dark claret-colored mass, which was the epididymis, twisted twice. A band of omentum was attached to, and lay around, the hilus of the testis, and this had evidently prevented a complete descent. It was torn through, and dropped into the abdominal cavity. The testis and epididymis were excised as high up as possible. No attempt was made to untwist, and the direction of the twist is not stated.

Case VI. (This case is from Czerny's Clinic at Heidelberg, reported by Dr. Edward von Meyer.)[2]—An Englishman, aged eighteen, who, three days before admission, was suddenly seized with an intense pain in the right testicle, close to the external abdominal ring, accompanied by a condition of partial collapse, small, weak pulse, vomiting, and a swelling. Diagnosis: Ruptured varix, and as there was some redness present, an incision was made. The sac contained, besides clots, the testis, twisted upon its axis and looking like gangrenous intestine. It was untwisted a turn and a half, direction not stated, and as the organ of the other side was in a state of atrophy, it was allowed to remain. Four months later the patient was examined, and the testis, which was hard, lay partly fixed at the root of the penis, and measured three by two and a half centimetres. The left was larger than normal and in normal position. The author did not think that in this case there would be a restoration of function, but would rather expect an atrophy.

Case VII. (Reported by Bryant,[3] of London, February 27, 1892.)—This case was not the second case published, as some of the English writers would lead us to believe, nor was that of Mr. Nash the first. The patient, a lad fifteen years of age, with a partially descended testis of the left side, after an attack of constipation lasting for five days, and a long bicycle ride two days previously, but with no accident, developed what was thought to be symptoms of strangulated hernia. Sudden pain during the night in the scrotum and groin of the left side, afterward reaching upward toward the umbilicus, accompanied by a swelling, part of which seemed reducible and gave to the finger a sensation of crepitation. Taxis was made under ether, with no result. Pain and swelling increased. The upper half of the scrotum, on the left side, with the whole inguinal canal to the internal ring, was swollen, the canal being filled with a tense, dull, fluctuating mass, in which there was no impulse. The gentlest manipulation caused pain. Bryant says he was by no means sure of his diagnosis. An exploratory incision showed a glistening coal-black object, which through the tunica looked like congested bowel, and which proved to be the testis engorged with blood. A torsion of the cord was found in the inguinal canal, untwisted by three half-turns inward, as also the usual dark fluid blood. The cord then looked like a bloated leech. As the testicle was still warm it was replaced, but subsequently atrophied. Bryant publishes with this the history of

Case VIII. (Dr. Keen, of Philadelphia.)[1]—Patient, aged twenty-three, who from birth had been troubled with a reducible, right oblique inguinal hernia, as also an undescended testis of the same side. Three days before admission to the Jefferson Medical College, he had an attack of vomiting, which did not recur, but was followed by constipation, and an increase in the size of the tumor. He tried reduction himself, but this caused pain and tenderness, and he desisted. Examination showed a mass in the inguinal canal, partly tympanitic and partly dull, with the skin inflaming. Diagnosis: Combined hernia and ectopic testicle. The hernia was reduced by taxis, and an incision made. The testis was found in the canal, anchored by a short pedicle one inch long, attached to the abdominal wall at the internal ring. Rotation, three half-turns. The small amount of fluid present had a slightly fecal odor. Keen did not endeavor to untwist, but removed the testicle, and sutured the walls of the canal and internal ring. He thought that without question the torsion was caused by the efforts of the patient to reduce the hernia, but although this may, and probably did, increase the trouble, other cases have shown that it can take place without a known active cause.

Case IX. (Davies-Colley.)[2]—Boy, aged fourteen. Right testicle had always remained in the groin. On the day previous to being seen he had, without known cause, pain in the groin, with vomiting and increase in the size of the swelling. On examination there was no impulse on coughing in the swelling, which was tender and the size of a hen's egg. Diagnosis: Strangulated hernia. Taxis on the third day, and no result. Operation four days after the first symptoms. The usual bloody serum and a black shining mass, resembling small leeches, connected by tight constrictions, were exposed, due to twisting of the cord, which was relieved by three turns to the patient's left, *i.e.*, inward. There was no hernia present, and no communication with the peritoneal cavity. The testis was allowed to remain, but afterward sloughed away.

Case X. (Herbert Page.)[3]—A boy, aged seventeen. Brought to the hospital on account of urgent symptoms in connection with a right congenital inguinal hernia, for which a truss had been worn. Without known cause he experienced during the night a severe scrotal pain, accompanied with swelling and tenderness. This was followed by vomiting (once) and constipation. On examination hernia was excluded. Operation, four days after the onset: The testis was found black and gangrenous, the epididymis greatly swollen and of a deep chocolate color, produced by a torsion of the cord, which was easily untwisted by two turns to the patient's left, from without inward. All dead tissues removed. Recovery normal.

Case XI. (E. Anders.)[4]—Patient, thirteen years of age, was seen (presumably for an incarcerated hernia) with a tense tumor in the left inguinal region, and left-sided cryptorchism. An incision exposed an eight-to-ten-centimetre long mass in the canal, with a broad pedicle, continued into a rigid internal ring. The sac, which only partly protruded through the external ring, and was tightly clasped by it, held a clear fluid and a blue-black tumor, the gangrenous epididymis, which was twisted, and which, when released by cutting the external ring, spontaneously untwisted itself. The testicle and part of the superfluous tunica were removed, and a normal recovery followed. He had carried a

truss for five years on account of a presumable hernia, and, perhaps, in his case, this had something to do with the production of the torsion, or the crowding of the imprisoned testicle into the ring.

Case XII. (R. W. Johnson).[1]—G. R——, twenty years of age, upholsterer, had had an inguinal hernia upon the left side. While blowing a cornet had felt the gut descend, followed by pain and vomiting. Two days later, when seen by Dr. Johnson, he had an irreducible, slightly painful tumor of the scrotum. The next day a suspicious "crackling" on pressure induced Johnson to cut down, after reducing part of the hernia under anæsthesia. The sac was found thickened, but contained no gut or omentum. Testis gangrenous and emphysematous from a series of twists in the cord, three half-turns from within outward. Testicle removed. Recovery normal.

Case XIII. (W. Gifford Nash).[2]—A school-boy, aged nineteen, an hour and a quarter after boxing felt a pain in the right testis and cord. In tracing up the swollen cord from the epididymis, Nash found a tender lump, the size of a cob-nut, one inch above the testis. Above this the cord was normal. The epididymis lay in front of the testicle. No urethral discharge. Diagnosis: Torsion of the cord. The epididymis was rotated outward and behind to its normal position, *i.e.*, one-half twist—180°. It remained so, and all pain and swelling disappeared. The next morning, with the exception of a slight hardening of the cord at the point of twisting, everything appeared normal.

A note by Nash in the *British Medical Journal* of January 19th last, referring to this case, says that the patient informed him eighteen months afterward that the "right testicle is considerably smaller than the other."

Case XIV. (A. E. Barker).[3]—Patient, fifteen years of age, whose right testicle had never completely descended and had always remained small. A hernia of the same side had been present since his seventh year. Immediately after a stool the hernia, which had come down, could not be replaced. He vomited twice on this and on the following days, went to bed on the fifth day, but was not sent to the hospital until the ninth day after the first symptoms appeared. There was local swelling and pain. Tongue dry; pulse, 96; temperature, 102.2° F. Right testicle, two inches below the external ring, considerably swollen. Skin dark and œdematous. Abdomen not sensitive. Had passed wind, but there had been no movement of the bowels for seven days. Diagnosis: Omental hernia. Operation: The sac contained bloody serum, with a few clots, and the dark, flattened, and livid testicle, which was twisted outward three half-turns. There was no hernia. Torsion released by three half-turns, and the testicle removed. Recovery normal.

Case XV. (Mr. E. Owen).[4]—School-boy, aged thirteen, in whom the left testis had never descended. Two days before, after bowling at cricket, a swelling had appeared, with pain and vomiting. Owen found a tender mass, the size of a hen's egg, just outside the external ring of the left side. No impulse. On dragging the tumor downward, the cord and external ring were found free and clear. It could not, therefore, be a hernia. Operation showed the usual blood-stained serum and a gangrenous-looking testis, which was removed, after which a twist, one half-turn outward, was discovered in what was apparently a second sac of the tunica above, which had been cut off by the twist from the main cavity; the twist being immediately at the top of the epididymis, and the cavity of the tunica unusually large. The testicle was freely movable, and Owen thought there was no mesorchium, which, as we will afterward see, is a condition which cannot possibly exist.

Case XVI. (Langton).[1]—This case was mentioned by Owen. Age not given. No history of injury. A painful tumor, the size of an orange, suddenly appeared in the left side of the scrotum. Cord free and normal above. An incision showed a twist, which could not be released. The testis and epididymis sloughed away. Recovery followed. The direction of the twist was not stated.

Case XVII. (C. Langenstein).[2]—Presents particularly interesting points. A laborer, aged twenty-five, whose right testis had never descended, while lifting a piece of heavy wood experienced a sudden sharp abdominal pain on the right side below, followed by vomiting and a number of movements from the bowels. Two days later, examination showed a painful swelling along Poupart's ligament on the right side, as large as a hen's egg, giving a short, empty, tympanitic note. Cremaster—reflex pain on the left side, absent on the right. Air passed the rectum, and urine voided spontaneously. Diagnosis: Probable torsion of the cord, but abscess from the appendix, or a mesenteric hernia in an interstitial congenital sac, could not be excluded. Three days later an incision along Poupart's ligament exposed a cavity beneath the obliquus externus, reaching from the pubic tubercle upward and outward to about two finger-breadths above the anterior superior spine of the ilium, lined with a serous membrane and divided into two chambers (by an adhesion), which contained bloody serum in the outer half, and the black and shining testis, with clots, in the inner. The epididymis was directed upward, and the testis downward, a twist of 180° inward, exactly at the insertion of the cord to the testis, which was easily released by placing the epididymis around and underneath, untwisting it outward. The pedicle or cord was of normal color, and, becoming broad toward its base, was inserted into the sac-wall below and in front, along the greater lateral half of Poupart's ligament. In this inverted fan-shaped funiculus lay the vas deferens toward its inner edge, while the outer and greater portion consisted of fatty tissue and veins only. As the testicle did not resume its natural color, and as there were inflammatory processes present, it was extirpated. No trace whatever could be found of either internal or external rings. The cord showed an old adherent torsion just at the head of the testis, as if it had at some previous time been twisted 180°, although it had never given rise to any symptoms. On section, the testis was found filled with blood and clots, but no trace of tissue structure and no thrombi were present in the vessels. Microscopical examination showed a high degree of hemorrhage into all the structures, both into the tubules themselves, and into the interlobular tissues. The cavity of the sac which lay between the layers of abdominal muscles neither communicated with the abdomen nor with the scrotum. This peculiar condition, as also the absence of the rings, was explained by the fact that it was a case of incomplete development, the testis having been arrested, on its way to the scrotum, in the canal, and the vaginal process having not yet sunk to the bottom of the scrotum, hence no external ring had formed and the internal ring had already closed. This is extremely interesting, and goes to prove Bramann's contention that the old idea about the formation of the gubernaculum is wrong, *i.e.*, that it reaches from the lower end of the testis, while it is still in the abdomen, to the floor of the scrotum, or develops immediately before the descent of the testis in this situation.[3] His examination, partly microscopical, partly macroscopical, has shown that even at the period of the greatest development, *i.e.*, the sixth month of fœtal life, it cannot be traced upward beyond the aponeurosis of the external oblique, and submits in proof dissections of six-months-old fœtuses, just before the beginning of the descent.

where he had dissected over the external ring down to the aponeurosis of the external oblique, which is shown as a thin and transparent membrane, but not broken through, and with nothing leading downward as a gubernaculum to the scrotum, which is fully formed and filled with connective and mucoid tissue. The testis at this time lying in close connection with the epididymis, being held in the same fold of peritoneum, the mesorchium, and sitting on the upper end of the gubernaculum, which is shown to lead downward toward the inguinal region, and enter the abdominal wall at this situation.[1]

Case XVIII. (E. Lexer).[2]—Reported at the Association of Berlin Surgeons, February 12, 1894. A mason, aged sixty, had had repeated attacks of swelling of the left testicle during the preceding three years, but never during earlier life. Two weeks before admission it came on again with severe pain, did not resolve as before, but increased rapidly in size. The scrotum on the left side was found filled with a tumor the size of a child's head, tense and fluctuating, with the skin adherent, red, and œdematous, its upper limit sharply defined on the cord. No especial pain at this period while in bed. The usual thickened tunica, bloody serum, and blackened testis were found, with a torsion of the cord inward of about 270°. The testis was flattened, and, besides being gangrenous, contained a large cyst adherent to it, and which took the place of, and which microscopical examination showed to be, the epididymis. The origin of this cyst was uncertain. Testicle removed. Recovery.

Case XIX. (Lauers).[3]—A boy, aged fifteen, had a sharp, severe pain in the left inguinal region, without known cause. Examination showed an hour-glass swelling in the left side of the scrotum, the upper part as large as a hen's egg, painful, and fluctuating. On operation, a torsion of the cord was found, direction not given. The nutrition of the testis was considerably affected and it was removed. Recovery.

Case XX. (L. Defontaine).[4]—A child of eight months, with a painful tumefaction the size of a pigeon's egg, in the left scrotal region, extending upward as far as the external ring, and which had been present since the night before, accompanied with fretfulness and vomiting. The testicle could not be made out. Diagnosis: Strangulated intestinal hernia. Operation, twenty hours later, showed a twisted cord, resembling very much in color, size, and looks what a strangulated gut in a child of this age would be. The testis was swollen, and twisted twice about itself. This was easily reduced, and the testis allowed to remain. Five and one-half months later there was an apparent atrophy. The direction of the torsion was not stated.

Case XXI. (W. Rennsen),[5] I have been unable to obtain an account of.

Case XXII.—The case which I have to present differs, as we have said, from those already reported, in that the torsion was reducible by the patient himself, and that it recurred much more frequently than those whose history also showed a recurrence, coming on as often as twice within twenty-four hours on several occasions. About eighteen months since, I was consulted by a recent graduate in medicine, twenty-five years of age, and at present an interne in one of the city hospitals, concerning a trouble with which he said he had been afflicted off and on for the preceding three years, having been just past twenty-two when it first occurred. He had been told by his father, also a physician, that at birth his right testicle had but partially descended, and did not reach the upper part of the scrotum until two or three years later. There had never been any hernia.

He stated that at irregular intervals, sometimes at night when asleep, but more frequently during the day when up and about, without apparent cause, without strain, undue exercise, or sudden movement, he would be seized with an acute pain in the right testicle, radiating upward along the cord and inguinal canal, and that on "feeling where the pain was," he would find the testis, epididymis, and cord swollen and extremely sensitive, the cord feeling hard and knotty to the touch. At the time of the first attack, not understanding the cause of the trouble, or the method of relief, he suffered for about two hours with intense pain, and finally, on lying down, the pain and swelling both subsided. This time he seemed to think his trouble was caused by wearing his trousers pulled up too snugly on the right side. After this, the attacks varied from twice within twenty-four hours to but once in four months, and at no time was he able to associate or connect any special movement or exertion with its coming on. From the subsequent attacks, up to within the time I saw him, he obtained relief by "pulling or stroking the cord upward," or "lifting the testicle upward," evidently allowing it to untwist, the manipulation lasting sometimes eight or ten, but latterly only two or three minutes, before the pain would subside. After the attacks he was never confined to his bed, but would immediately be up and about. Since realizing the nature of the trouble, it has happened but three times during the eighteen months, on which occasions he has endeavored to examine the conditions more closely, but the pain has each time been so acute that a prolonged examination has been impossible, and as at this period he understood quite well how to obtain relief in a very short time, he was rather loath to calling in outside aid, fearing that matters might be made worse. He has found, however, that the twist on these three occasions has been from right to left, *i.e.*, from without inward, and instead of "lifting up the parts," or "pulling upward on the cord," he has succeeded in relieving the torsion by twisting from within outward, and has found that the whole organ has been twisted two full turns upon itself, and that it has made two complete circles with the cord as its axis.

On examination I found the following condition: The right testis was of about the same size as the left, the usual difference as regards the situation of the two being exaggerated, the left being well down to the bottom of the scrotum, while the right hugged the upper wall, and seemed drawn upward toward the inguinal canal. On attempting to rotate, I found that I could make three complete half-turns in either direction, without causing the slightest inconvenience or pain; but if held in this position for a minute or more, the veins of the cord became swollen and hard, showing an evident obstruction to the return circulation. Beyond this point it was possible to twist still more, about one-fourth of a circle, when the manipulation became painful and I desisted. When left to itself it would remain in this position. The left testis admitted of a rotation of a little over one complete circle, but when left to itself it would return to its normal position. Five months ago, an incomplete, reducible inguinal hernia developed upon the same side, which is easily retainable in the abdominal cavity by means of a truss.

When we come to look at the causes of this accident we find that they are both predisposing and active.

All, excepting Nicoladoni's second case, sixty-two years of age; Lexer's case, sixty years of age; and Defontaine's, aged eight months, have occurred either in young men or boys, with ages ranging from four to twenty-five years, most of them being at, or shortly after reaching, the age of puberty, about at the period of greatest activity, after the testis has become of size. One condition, or predisposing factor, it seems, is absolutely necessary, and without which it would be impossible for a torsion to take place, *i.e.*, the absence of fixation of the testicle by means of the peritoneal reflex, the

mesorchium, so that it hangs freely on a pedicle, which, at any rate, is not fixed for some distance. This explains in itself the necessary anatomical conditions under which the twisting can be complete. Nicoladoni lays special stress upon this point, the absence of a short fixation, by a short mesorchium. The origin of this abnormal condition, which shows itself either as a too slender or too long, or as a complete absence of fixation, is to be traced back to early disturbances in the development of the processus vaginalis, and the shortening of the gubernaculum, which takes place at the same time.[1] As the abnormal formation of the mesorchium allows great movement to the testicle, it can, hence, make difficult the entrance of the testicle into the inguinal canal, and in this way be the cause of late or incomplete descent. Kocher has shown two examples of this kind.[2] In fact, the majority of cases have been with incomplete descent, and in many of them this abnormal condition has been mentioned. Nicoladoni says, "The expressions 'absence of a mesorchium' and 'too long a mesorchium' do no not refer to opposite conditions, although apparently we might think so. In no case is there an 'absence' of the mesorchium, for as the testicle already has a peritoneal covering before its descent, while in the posterior part of the abdominal cavity, the mesorchium cannot possibly be absent after it has descended. Hence, the cases described as 'absence of the mesorchium' mean only that the testicle is deprived of its normal fixation, while a 'too long mesorchium' relates as well to the cord as to the peritoneal covering both of itself and testicle."

Besides this, according to Lexer, we have another important predisposing factor, as well for the occurrence of the torsion as for the impossibility of its untwisting itself, especially when the testis is in the canal, and that is, its flattened shape, to which attention was drawn in several of the cases. With this condition present it can be understood how certain, perhaps unusual, movements of the body and lower extremities can become the direct cause of the torsion, and, if having once taken place, how difficult it would be for the testicle to resume its normal position. So, during heavy work, as in Nicoladoni's second case, and in Lauenstein's, after lifting a heavy piece of wood.

It has been impossible, however, in all cases to discover a direct cause, for although, besides these two, we find Whipple's coming on after a strain, von Meyer's after sneezing, Johnson's while blowing on a cornet, Nash's after boxing, Barker's after straining at stool, and Owen's after bowling at cricket, yet there are a number where nothing whatever unusual had happened, as in those of Keen, Davies-Colley, Page, Anders, Lexer, and in my own; in fact, in several, the first symptoms appeared while the patients were asleep. In several, where the pain came on only some time after the accidents which were supposed to have caused them, it looks as if the torsion had perhaps commenced at the time of the accident, and had afterward been completed by subsequent bodily movements; that is, completed sufficiently far to cause a disturbance in the circulation of the cord and testicle. For testes which lie in the scrotum the conditions would be different from those where they lie horizontally in the inguinal canal, and in this connection Meinhardt Schmidt has drawn attention to the fact that we have an analogue in the torsion of ovarian tumors, which certainly finds some causation in mechanical acts, such as changes in position from movements of the body and intestines. We naturally get more torsion with a long mesorchium than with a short one, but violence *per se* is not necessary. Any slight movement may complete the amount necessary to interfere with the circulation, which varies in the individual cases.

Pathology.—As we have seen, in all cases where the vaginal process was opened there was a greater or less quantity of bloody serum and clots. The testis and epididymis were congested and swollen, of a dark or bluish-black color, and sometimes in a more or less advanced state of necrosis. Sections of testis showed it filled with blood and clots, with sometimes no trace of tissue structure, as in Lauenstein's case, while microscopically there was a true hemorrhagic infarction, a high grade of hemorrhage, or overfilling with blood of the entire organ, both of the lobules themselves and of the interlobular tissue. The necrosis, when present, was especially marked at the periphery. This condition of hemorrhagic infarction is well explained by Miflet's important work,[1] in which is found the foundation for a complete understanding of the consequences of torsion, as far as is possible, by experiments upon animals.

He used eighteen dogs, as follows: In seven he made artificial emboli; in four he ligated the internal spermatic artery; while in five he ligated both the internal spermatic artery and veins; and in two the veins alone. In two of the first seven the deferential artery was also stopped. These are his general conclusions and results:

1. The internal spermatic artery has, for the testis, the significance of a terminal artery.

2. Interruption of the flow of blood through the internal spermatic artery, either by ligation or by embolus, is quickly followed by the formation of a hemorrhagic infarction, and these infarctions involve especially the superficial layers of the testis.

3. The glandular structure of the testis is especially sensitive to any disturbance in the circulation of the cord, not only when both the arteries and veins are interfered with, but also when the circulation through the veins is interrupted. The glandular tissue always disappears rapidly, which change takes place with more or less tissue proliferation.

4. The epididymis, which is supplied by the deferential artery, is not at all affected by ligature, and very little by embolus.

5. If at the same time the circulation is disturbed in both the spermatic and deferential arteries, then the secreting tissue of the epididymis is also destroyed.

As to the torsions themselves; where stated, the accident happened twelve times upon the right side, and nine times upon the left; the greater length of the left cord, therefore, not having increased its liability, but, on the other hand, the twisted cord has always been abnormally short, the testis either lying within the inguinal canal or high up in the scrotum. The direction of the twist, however, when mentioned, has been nine times from without inward, and but three times from within outward. Lauenstein mentions this point, as resembling the idea brought forward by Küstner, as regards the torsion of ovarian tumors, that the pedicle of the tumors of the right side had a left twist, and those upon the left side had a right twist. The degree of torsion sufficient to cause strangulation has varied greatly, from a half-turn in Keen's and Nash's cases, to two full turns in Defontaine's and my own; for, as we have seen, a long mesorchium would permit more twisting to take place, before the circulation would be interfered with, than a short one.

Symptoms and Diagnosis.—In most cases there have been more or less well-developed symptoms of inflammation, such as pain, local swelling, and, in some instances, œdema, redness, and fever; and when we find these conditions associated sometimes with constipation and vomiting, together with absence of impulse in an irreducible swelling, developing suddenly, after perhaps some strain or exertion, we are naturally led to suspect a strangulated hernia. There are, however, some distinctions. With torsion of the cord the constipation may not be absolute. The vomiting, which is not apt to become stercoraceous, is not so persistent.

The shock is less, and there is not so much abdominal distention nor pain at the umbilicus. In fact, these latter may not be present at all. Again, the tumor, especially if outside the external ring, is apt to be harder and more solid to the touch, and if the seat of torsion is below the ring, the swelling would not extend into the canal, and the finger passed through the ring would, in this case, be able to clear up any doubts. Still, as we have seen, a correct diagnosis may at times be extremely difficult and impossible before making an exploratory incision, especially where we also have a hernia present. Abscess from an inflamed appendix, as also gonorrhœal and traumatic inflammation of the testis and epididymis, should not be forgotten.

Treatment.—If left alone there would probably be either one of two results—atrophy or gangrene. In this connection Chaveau's experiments on goats are interesting. He found that after a subcutaneous torsion of the cord the testis would atrophy, and that gangrene only occurred in cases where he had previously introduced substances into the circulatory system which had undergone putrefactive changes. Atrophy is not a very infrequent result following the subcutaneous operation for varicocele, and it is well known that the surgeon Delpech was killed by a patient on whom he had operated for double varix, and who afterward had atrophy of both testes. As Nash says, "It will probably not happen very often that surgeons will be fortunate enough to see cases at their commencement, but now that the accident and its causes are becoming generally known, they will at least be prepared for it, and some will undoubtedly be recognized in time to be untwisted." In all cases where castration has been performed there has been a good recovery, and this would be much earlier resorted to where we have a testis in the inguinal canal, as it is well known that they are apt to become sarcomatous if left in this situation. In eight cases the testis was not removed. Two of these were untwisted without operation, followed by atrophy in one. In three the testis sloughed away during healing. In two, there was subsequent atrophy; and in one, five months after operation, there was no change except that it was harder than normal, and fixed by adhesions at the root of the penis.

I record still four cases* which, without doubt, were results of this accident, but where the torsion was not discovered; and I am especially indebted to the papers on the subject by Lauenstein and Lexer.

36 West Thirty-ninth Street.

THE ADMINISTRATION OF THYMUS IN EXOPHTHALMIC GOITRE.

By R. H. CUNNINGHAM, M.D.,

ASSISTANT DEMONSTRATOR OF PHYSIOLOGY, COLUMBIA COLLEGE, NEW YORK.

Apropos of a report by David Owen, in the *British Medical Journal* of February 16, 1895, of a case of exophthalmic goitre that was successfully treated by the accidental administration of the thymus gland, a survey of the benefits derived from the administration of minced thymus in the following cases of that disease will additionally tend to show that in certain cases, at least, of exophthalmic goitre a diet of thymus may be followed by results that are surprising, gratifying, and very suggestive.

The first of these cases, whose history I give in full detail from my private case-book, was under my personal observation for eighteen days only. She has, however, reported her progress to me by letter a number of times since I saw her. Since treating her, several other cases have come under my observation, two* in the Department for Nervous Diseases at the Vanderbilt Clinic, and the others in private practice, and all have been treated either with the fresh gland or with thymus tabloids. These cases are still under treatment with the thymus; nevertheless from the improvement that has occurred in one or more of the symptoms, even in a few weeks' time, I feel justified in adding them to this report.

Case I.—Miss B——, aged twenty, consulted me, October 2, 1894, stating that several physicians whom she had consulted had told her she had Basedow's disease. She consults me now to get something to make her sleep, as she has been unable to sleep for the past two nights, and also because she has felt so extraordinarily weak for the past few days.

Her hereditary history is noteworthy. Her deceased father had prominent eyes, was a sufferer from insomnia, and had died of pneumonia two years ago. Her paternal aunt had prominent eyes, and also a slight swelling in the neck. She had frequently complained of palpitation of the heart and of general weakness. The patient's mother says the doctor who attended her stated that her death was due to "heart trouble." Miss B——'s brother, aged twenty-five, has a tendency to prominent eyes, but is strong and active.

Except for an attack of measles at fourteen years of age, Miss B—— had had good health until two years ago. A short time after her father's death, at which she was very deeply grieved, she began to suffer from palpitation of the heart on the least exertion. From that time her eyes have gradually become more prominent, though she has been seriously troubled with insomnia for the past year only. In addition to the above she complains of a loss of energy, mental depression, excessive sweating on the right side at night, sensations of "flushing," trembling of the hands, and occasional headaches, but has had no aural disturbance. Her appetite is poor, and her bowels are usually constipated.

The examination showed a fair amount of exophthalmos, both Von Graefe's and Stellwag's symptoms being present. The inco-ordination on convergence was slight. The apex-beat of the heart was strong, 124 per minute, regular, and was not displaced, nor was there much evidence of hypertrophy. The lungs were apparently normal, and no abnormality could be made out in the region of the thymus. The thyroid was moderately enlarged, soft, and compressible, but no enlarged accessory thyroids or lymph glands were present. A moderate bruit existed over the thyroid. She appeared slightly anæmic, and the result of the examination of the blood was as follows: Red corpuscles, about four million six hundred thousand per cubic millimetre; white corpuscles (not counted); hæmoglobin, sixty per cent. (Von Fleischl's hæmom). Microscopically nothing worthy of remark was noticed. The urine was 1.022 specific gravity, and negative. She was put on the thyroid tablets, one tablet (gr. v.) *t.i.d.*, and, in addition, trional was prescribed for the insomnia.

October 4th.—She states she feels worse and has slept no better than before. The heart-beats had increased to 136 per minute, and were also irregular at times. The respiration was 28. The thyroid tablets were discontinued, and later in the day arrangements were made with a butcher to supply her daily with a fresh thymus from a healthy lamb that had been brought up on milk. This was to be minced fine and taken raw if possible.

October 10th.—She returned and stated she had been unable to take it raw as it made her sick at her stomach and she could not retain it. Therefore she had

*1. H. H. Johnson: Boston Medical and Surgical Journal, 1888. 2. Bramm: Langenbeck's Archiv, 1890, p. 163. 3. Erichson: 8th edition, vol. ii., p. 813. 4. Volkmann: Berliner klinische Wochenschrift, No. 53, 1887.

* For the privilege of referring to these in this report the writer is indebted to Dr. Frederick Peterson, Chief of Clinic, Department of Neurology, at the Vanderbilt Clinic.

taken it broiled very slightly. At this date the heart was 120 and regular, the respirations 20 per minute. She says she has slept a little better, but no change except that noted above is perceptible.

October 20th.—I saw her for the last time, as she and her mother were unexpectedly compelled to return to her home in a neighboring State. She stated she had slept very well for the past few nights (no trional or other hypnotic had been taken since the 10th) and had taken the thymus uncooked for the past three days without nausea. The pulse was 100, the respirations 18.

Since October 20th her mother has written to me a number of times to inform me that her daughter has steadily improved, and in the last letter written by Miss B——, on March 10th, she writes that she feels as well as she ever did, that the swelling in the neck has disappeared, and that she can take a considerable amount of exercise without getting fatigued. Her pulse is about 72 and she sleeps as well as she did before her trouble commenced. Her mother tells her that her eyes are no longer prominent and that the color has returned to her cheeks.

Case II. has, unfortunately, not followed the treatment very regularly; sometimes neglecting to take the glands for several days at a time, but he has nevertheless considerably improved in many respects. Briefly summarized, the most prominent symptoms presented by him were a general diminution of energy, severe insomnia, palpitation of the heart, fatigue and moderate dyspnœa on the least exertion, prominent eyes with lagging of the upper lids on looking downward, and a slight horizontal nystagmus on rapid convergence, a slight increase in the size of the thyroid, pulse from 100 to 110, and a well-marked, fine-waved tremor of the hands. The above symptoms had been becoming progressively more prominent during the past four years. After an irregular administration of slightly cooked lamb's thymus for two weeks the pulse-rate had fallen to 78 per minute and was perfectly regular. He slept very much better, and was feeling stronger. His eyes had become much less prominent, and only after a very searching examination was a slight degree of Von Graefe's symptom found to be still present. When I last saw him his eyes were apparently normal, his pulse was 76, his capacity for hard work had greatly increased, and the tremor of the hands had entirely disappeared.

In a third case that presented the usual symptoms of exophthalmic goitre the thymus gland tabloids of Messrs. Burroughs, Wellcome & Co. have been administered at the rate of twelve to fifteen 5-grain tabloids per day and have been followed by improvement, especially as regards the ocular symptoms. In this case after a week's treatment with the tabloids in the above dose a very considerable decrease in the enlarged thyroid occurred. This diminution still continues to slowly progress. Two and a half weeks after the tabloids were begun, the pulse-rate, which in the beginning averaged about 124 per minute, had become 96, though it would readily mount to 120 after moderate exertion or excitement. She feels, however, much stronger, and has been able to resume her work.

Possibly had a larger number of the tablets been given a more rapid and marked effect would have followed. At present she is taking the fresh thymus gland and the results of this procedure the writer will give in detail in a later paper on this subject.

If the results following the administration of thymus in these cases be compared with those published by Owen,[1] I think one may reasonably exclude the factor of mere coincidence, for though cases of Graves's disease do get well sometimes without any treatment whatsoever, Owen shows the suppressed symptoms began to return when the administration of the thymus was discontinued.

The remarkable and rapid diminution of the increased heart-action and the progressive abatement of the other symptoms would certainly lead one to believe that by administering the thymus via the gastro-intestinal tract some substance that influences the deranged metabolism in a peculiar and striking way has been added to the blood.

The present state of the knowledge of the physiological chemistry of the thymus gland certainly does not help one to form a definite idea as to what this substance may be. It is true that Schindler has shown that a high percentage of adenine, a base derived from nuclein (Halliburton[5]), exists in the fresh and in the dried thymus of the calf; but whether the extractives or the nuclein (Kossel[6]) or the derivative base, adenine, of the thymus are the chemical bodies or not which act in exophthalmic goitre in a manner analogous to that attributed by Goulay[7] to the nucleo-albumin of the thyroid body when the latter is given in myxœdema, one has not sufficient evidence for positively stating.

A brief look through some of the scanty literature of the experimental results obtained from depriving young animals of the thymus would lead one to believe that the presence of the thymus gland in the lower animals is not a necessity for the well-being of those animals, provided we are ready to accept the results of those observers as finally conclusive. Though Langenhaus and Saveliew[8] got negative results in the dogs and rabbits that survived after extirpating the thymus, it is difficult to reconcile such results with the apparent physiological activity of the said gland in certain orders of young animals. The deaths of many of their animals resulted, according to the authors, from gastro-intestinal disturbance consequent to "too much green food" in the case of the rabbits, and in the dog worms were found in the intestine. No definite systematic information, however, is given regarding the character of the diet from first to last, and this, in my opinion, is an important omission when one takes into consideration the difference between the large, well-developed thymus of a calf or of a lamb that has been brought up on milk, and the small, atrophied thymus of a calf of equal age that has been weaned early and fed on grass. Further details on this score will be submitted, however, in another paper.

In 1893 Macalister[9] called attention to the remarkable metabolic effects that occurred during a diet of thymus in a case of pseudo-hypertrophic paralysis, and his results would tend, to say the least, to substantiate one of the ideas of some of the older writers,[11] that the thymus stands in relationship with the state of development of the muscular system In exophthalmic goitre also many symptoms are manifested by the muscular system that possibly arise from the action of the pathologically altered product of the thyroid which Lemke[13] states is a specific muscle-poison that separates the normal tonus into many small contractions.

But does the thymus add to the blood a special substance that has an "oppositeness" of action to the hypersecretion of the thyroid, or to some poisonous substance occurring in the blood consequent to the qualitative alteration of function of the thyroid? Possibly, as Owen suggests, though I do not unite with him in bringing forward the "oppositeness" of action that is claimed by Zanda,[11] on repeating Bardeleben's (1841) experiments, to exist between the spleen and the thyroid, as a reason to strengthen the probability of this possibility, for Fano[15] was unable to corroborate Zanda's statements, and the writer on repeating Zanda's experiments, using young and middle-aged dogs, finds also that the consequences of total thyroidectomy, after previously extirpating the spleen, are the same as in animals who possess the spleen intact. As Breisacher first pointed out, when thyroidectomized dogs are fed on meat that has been thoroughly extracted by boiling, the appearance of the cachexia is much delayed; if, however, the dogs are fed on the

bouillon from the meat, the cachexia rapidly develops. The writer has, on the other hand, fed thyroidectomized dogs on thymus without apparently hastening or delaying the appearance of the cachexia otherwise than if the animals had been fed on so much ordinary cooked meat. Nor have I ever seen any diminution in the symptoms of exophthalmic goitre follow a diet of underdone meat, provided no other therapeutic means were employed at the same time.

That a functional relationship, at present unknown, does exist between the ductless glands is manifest from the results both of experimental investigation and of clinical observation. Thus the compensatory (?) hypertrophy of the thyroid that occurs after extirpating the spleen is well known. According to Cadéac[38] enlargement of the thymus follows thyroidectomy in lambs. Likewise, Rogowitsch[16] has found that after the thyroid has been removed in rabbits, the pituitary body becomes enlarged. Clinically, Boyce and Beadles[17] emphasize the frequency of the same occurrence in myxœdema, sporadic cretinism, and cachexia thyreopriva in man. In acromegaly[28] hypertrophy not only of the hypophysis, and either hypertrophy or atrophy of the thyroid occur, but an hypertrophy or a "revival" (Marie[18]) of the thymus has often been reported. In myxœdema, and especially in exophthalmic goitre,[18] a similar hypertrophy or revival of the thymus is frequently found, as is evident from the cases of the latter disease reported by Johnston, Hale White, Mosler, Spencer, Marie, Moebius, Lasvenes, Reymond,[34] and several other observers.

The possibility of the participation of the quantitatively or the qualitatively altered internal secretion (?) of such glands, whether hypertrophied concomitantly with the thyroid or secondarily to the thyroid, as a causal factor of some of the symptoms in certain cases of exophthalmic goitre is therefore worthy of consideration. That the increased secretion of the thyroid is not the sole producing cause of the whole complex of symptoms of exophthalmic goitre many eminent observers concede. A mere glance at the final results of surgical interference with the enlarged thyroid that occur in certain cases of this disease will show that such is correct.

Briefly summarized, these surgical results may be stated to be as follows:

After partial extirpation of the supposed hypersecreting thyroid a complete (?) cessation of the symptoms occurs in one set of cases. In the second set merely a temporary moderation[30] of the symptoms has followed, and this moderation has been succeeded in a short time by an increase even in some of the former symptoms.

In other cases no immediate or remote diminution in the symptoms has resulted from the operation.

Lastly, the operation has been followed in a number of instances by fatal results which were accompanied by the symptoms of acute thyreopriva in some cases, while in others the cause of death was attributed to the "inundation"[19] of the system by the large amount of thyroid juice that was unavoidably introduced into the circulation by the necessary manipulations of the operation.

Equally suggestive are the results of the observations both of clinicians and of recent experimenters. Among the clinical reports of sundry diseases treated by the administration of the thyroid extract the most striking in this connection is by Béclére.[23] According to this observer, after a myxœdematous patient had taken 92 gm. of thyroid extract in eleven hours, the symptoms of the myxœdema disappeared and were replaced by the symptoms of "intoxication," which consisted of tachycardia, instability of the action of the heart, fever, insomnia, agitation, incomplete paraplegia, increased respiration, exophthalmos, and fixedness of look.

A practically similar though less marked effect has been noted by a number of writers to follow the administration of large and repeated doses of the thyroid extract, but nothing definite as regards the artificial production thereby of a goitre is mentioned except by Ballet and Enriques.[24] These investigators state that after injecting the thyroid extract into dogs they succeeded in producing fever, tachycardia, tremor, and in addition a goitre; all of which disappeared when the thyroid was discontinued, but reappeared when it was readministered. It is true such injection experiments are complicated, as Horsley[25] pointed out some years ago, by the presence of toxic tissue fibrinogens, and due allowance must be made therefor. The writer has, however, fed dogs with enormous quantities (50 gm. per day) of commercial thyroid extract, also with 100 to 200 gm. of fresh thyroid daily for fifteen days, but so far with a negative result.

On the other hand, cases of exophthalmic goitre that have been treated with the thyroid extract have improved[26] instead of becoming worse. Such improvement results, according to Kocher,[19] from the "thyreoidin" causing a retrograde metamorphosis of the hypertrophied thyroid, and as the thyroid disease is not always primary, it is in this way beneficial. The most natural way, and the one more in accord with the evidence above, is that a sufficient quantity of a proper quality of the so-called "thyreoidin" is added to the altered blood, and by this addition some of the symptoms of exophthalmic goitre are caused to disappear, while others are moderated only, or even unaffected, and in some instances slightly, or even greatly, increased. In this connection those cases[30] which present at the outset the symptoms of exophthalmic goitre, later the symptoms of a combination of exophthalmic goitre and of myxœdema, and finally of myxœdema alone, are very interesting; likewise the case of Jeanselme[27] in which exophthalmic goitre and scleroderma coexisted. Similarly acromegaly and myxœdema, or cretinism and acromegaly, are well known to occur in combination.

Lastly, we are confronted with the fact that cases of exophthalmic goitre exist in which the administration of thymus is followed by a disappearance of the symptoms and by a recurrence of them, as in Dr. Owens's case, if the thymus is discontinued. This latter factor, as I stated above, certainly negatives the idea of the mere coincidence of spontaneous improvement. Likewise no variation of the ordinary diet except the addition of the thymus was resorted to in the cases under my observation, and though a moderate improvement, which disappeared when a meat-diet was resumed, has been observed to follow the employment of a milk-diet,[36] either with or without special attention to the correction by drugs of the disturbed digestion, the effects possibly resulting from this source are reduced to a minimum.

It will be noticed from the description of the cases reported by myself that they, as well as Owens's case, are evidently not of the type that is secondary to an ordinary hypertrophied thyroid and what the ultimate effects of the thymus administration will be on the symptoms exhibited by this latter class of cases, the writer is unable at present to state definitely; but judging from the apparent absence so far of any effect in several such cases that have lately come under his observation, probably no very great improvement will ultimately result.

A consideration of the above evidence and a careful comparative study[4,10] of the similar and of the opposite objective and subjective symptoms that are met with in exophthalmic goitre, acromegaly, and myxœdema, or in the combinations of these diseases, will lead one reasonably to conclude that the alteration that frequently occurs in one or more of the ductless glands besides the thyroid possibly plays a more or less prominent part in the causation of some of the symptoms of the disease (or possibly diseases(?)) to which the terms exophthalmic goitre, Graves's disease, and Basedow's

disease are applied. But whether the alteration of these glands, for instance of the thymus, is primary, concomitant, or secondary to a primary derangement of the nervous system (Marie), or to a toxic blood state induced by the functionally altered thyroid (Moebius), or by various "toxins" of gastro-intestinal origin, are questions which possibly may be explicitly answered in the future when a more definite knowledge of all of the functions and of the effects of disordered function of the individual ductless glands has been obtained from clinical observation and from further experimental investigation.

REPORT OF AN EXPERIENCE WITH ANTITOXIN AT THE NURSERY AND CHILD'S HOSPITAL.[1]

By ALLEN M. THOMAS, M.D.,

Attending Physician, Nursery and Child's Hospital, New York.

Since the date of an epidemic of diphtheria in the hospital in the fall of 1893, there has been from time to time an occasional outbreak in the wards. In January of this year, with the aid of fresh invoices from without, another epidemic was started associated with more or less of measles and broncho-pneumonia. These conditions so complicate the histories, and a close personal knowledge of the cases being impossible on account of my obstetrical obligations, I regretfully refrain from any attempt at reporting them. Dr. J. J. Mapes, the house physician, who has given to all this work his intelligent and close personal attention, may be able to do so at some future time.

The following report is consequently limited to an account of the antitoxin immunization in regard to which the facts at hand came under my personal observation, are uncomplicated, and surely simple enough to be beyond the likelihood of misstatement or misconstruction. I present them without further comment as follows:

Total number of cases in the hospital from January 18th, the time of outbreak, to April 18th, the date of immunizing, 46. In all these cases cultures of the Klebs-Loeffler bacilli were obtained, and observations of them doubly verified in most cases by the separate examinations of the Board of Health and Dr. Mapes. In 30 of these 46 cases abundant local clinical aspects existed, there being well-marked pseudo-membrane in the throat, nose, or larynx; the remaining 16 cases had only sero-purulent or sero-sanious nasal discharges as a local manifestation. Of the entire number of 46 cases 15 occurred between April 1st and April 18th, and 7 between April 11th and April 18th, plainly showing the epidemic to be gradually on the increase in the hospital up to the day of immunizing. On April 18th 30,000 units of antitoxin were obtained from the Board of Health, and 110 children immunized. On April 20th 26 more children were immunized, and the 32 remaining children in the hospital that had previously had throat or nose lesions containing Klebs-Loeffler bacilli were not immunized. Of these cases immunized the following table shows the age, number, and antitoxin units:

Age.	Number.	Antitoxin Units.
3 to 4 weeks	7	50
2 months	12	50 to 75
3 to 6 months	30	100
7 months to 1 year	22	150
2 to 4 years	59	200

Careful examinations were made individually for albumin, variations of temperature, and skin lesions, in connection with the general observation of the children as a whole. A few (4) showed faint traces of albumin in the urine, but this in no case (where the urine could be regularly obtained) persisted more than three to four days, nor was there in any case any rational symptoms pointing to any special disturbance of the kidneys. Three cases, eight days after the injections, and 4 cases, nine days after the injections, had an eruption, more or less profuse, of erythematous patches of the size of a silver dollar, in some isolated, in others running together about the head, trunk, and extremities; but in no case were they associated with any appreciable fever; in this respect markedly differing from cases that have been reported of erythematous eruptions occurring with rather startling elevations of temperature. Red, pea-sized, shotty papules appeared rather profusely on the face, in one case on the eighth day, and in another on the ninth, and the same kind of papules appeared on the face and both arms in a third case, also on the

[1] Read at a meeting of the New York Clinical Society.

ninth day; these likewise were associated with no rise of temperature.

The only temperature which occurred following the injections that could be accredited to antitoxin (one case with persistent high fever proved to be measles) happened within the twelve hours immediately succeeding the injections, and stood as follows:

In from six to twelve hours after the giving of the antitoxin the temperature rose, in the cases of children who had been previously normal, to

100°	plus	in	17	cases
101°	"	"	32	"
102°	"	"	16	"
103°	"	"	4	"

That is, in 69 cases out of a total of 136 children immunized the temperature rose within twelve hours from 100 to 103° F., but within the next twenty-four hours it had in all these cases virtually fallen to the normal. The amount of reaction, as manifested by rise of temperature, crying, restlessness, and sleeplessness, seemed to be directly proportionate to the youth of the infants, and to their general debilitated condition; while the stronger and older ones showed little reaction, scarcely being disturbed at all, many of the younger infants, especially the marasmic ones, cried all night, going almost entirely without food or sleep for twelve to fifteen hours.

No new case has broken out in the hospital since April 18th, the day of immunizing, with the exception of the assistant physician on the resident staff, who about three weeks after the children were immunized, and one of the ward nurses, who five weeks after, developed well-marked cases of tonsillar and pharyngeal pseudo-membrane, with both clinical and bacteriological evidences of true diphtheria. Neither had been previously immunized. This would seem to show very conclusively the continued presence of diphtheria bacilli in the hospital, and will make subsequent observation of the children still more interesting and instructive.

The conclusions, which seem not only justifiable, but fairly inevitable, to be drawn from this report are as follows: 1. The evident value of antitoxin in affording a certain period of immunity against the infection of diphtheria. 2. The apparent harmlessness of its use in this way with children even of tender age and condition.

May 28, 1895.

NOTE.—During the epidemic four nursing babies went to the diphtheria ward with their mothers who were suffering with diphtheria. These babies were all injected and then stayed from two to three weeks constantly exposed to diphtheria without contracting it.

An Ingenious Medical Man.—One of the most novel methods which has come under our notice for bringing one's name "under the notice of the public" was recently adopted, as we learn from a French contemporary, by a medical man in Montpellier. Desiring to practise in the town, he set himself to work to conjure up a scheme for informing the inhabitants that he was quite prepared to attend to their ailments. After mature consideration he decided upon the following ingenious plan: He engaged the services of the town-crier, and instructed him to announce throughout the town that Dr. So-and-so, giving his address and full qualifications, had lost a valuable dog, and that anyone finding and returning the same to the owner would receive a reward of £25. It soon happened that the subject of the lost dog became widely discussed, as well as the owner who had incurred the loss. The conclusion was arrived at that he must be wealthy, owing to the large reward offered, and the latest information is that the dog has not been found, but the ingenious practitioner has now plenty of patients.—*Medical Press.*

Progress of Medical Science.

The Permanent Results of Symphyseotomy.—Sufficient time has now elapsed since the wide adoption of symphyseotomy by antiseptic methods to furnish data which will assist in estimating the permanent results of the operation. As most of the patients requiring the operation are dependent on their work for a livelihood, it becomes a serious matter to ascertain the condition of health as regards ability to work which can be promised to these patients in selecting this operation. The reports from Schauta's and Gustav Braun's clinics by Von Woerz and Richard Braun (*American Journal of the Medical Sciences*) afford data of value upon this question. Von Woerz reports ten symphyseotomies performed some time previously, most of the patients being still available for observation. Of the 10 patients, 1 died of sepsis after the operation; 6 are in good condition, abundantly able to work without inconvenience: 1 could not be followed after leaving hospital care; 1 cannot stoop to work on her hands and knees without pain in the sacro-iliac joints; 1 suffered from incontinence of urine, which was cured by taking cold baths. Braun reports 8 symphyseotomies, and of these none died; 6 are now in good condition, working without inconvenience; 1 suffers from incontinence of urine and sacro-iliac pain on heavy lifting; 1 has incontinence of urine on straining and lifting. In Von Woerz's cases 5 were treated by drilling the symphysis and wiring with silver wire; in 4 the wire suture could not be successfully applied, and 1 had no suture. While good union is possible without suture, yet suture is preferable. Braun treated his cases with drilling and wiring, 3; with suture of the periosteum, 4; and without suture, 1. There seemed to be no difference in the result in these cases. From these cases the conclusion may be fairly drawn that symphyseotomy under good surgical care is an operation undoubtedly saving fœtal life at no serious risk of death or permanent disability to the mother. In view of the excellent results obtained without drilling and wiring the symphysis, the procedure is unnecessary.

Acute Perimeningitis.—Acute perimeningitis is an inflammation of the cellular fatty tissue around the cerebral dura (*The New York Medical Journal*). Its evolution is sometimes acute, spontaneous, with no appreciable pathogenic cause, and sometimes secondary, with cellulo-muscular inflammation near the spinal column. The symptoms resemble those of inflammation of the medullary meninges. It begins with sharp pains, with alternate remissions and exacerbations, in the legs and along the spine, and they are accompanied by stiffness of the limbs or of the neck. At the same time there is febrile movement with constipation. Subsequently there are pains in the abdomen and in the lumbar region, also in the legs. During the suppurating period, when the spinal canal is invaded with pus, the disease becomes infectious; sometimes paralysis sets in, and death takes place in a short time. In this evolution the meningitic symptoms may fail to show themselves, and the diagnosis is consequently rendered more difficult. The idea of cerebral meningitis, however, may be dismissed in the absence of the meningitic tripod, of ocular complications, and of the typical course of the temperature. Cerebro-spinal meningitis is epidemic and associated with infectious localizations in the lungs and in the heart, and its characteristics are distinct from those of acute perimeningitis. In the diagnosis of spinal meningitis great difficulties often arise, although in the beginning the early development of paralysis is a symptom of the disease. If it appears later on, there is reason to believe that it is a question of acute perimeningitis. Perimeningitis may be confounded with typhoid fever, osteomyelitis, and rheumatism. For this

reason, in the analysis of the symptoms, we should bear in mind that perimeningitis shows three different types in the beginning: A subacute type, with violent invasions, chills, headache, and renal pains; an acute type, the first symptoms of which resemble those of lumbago, and which is accompanied by insomnia, pains, cramps, and febrile movement; and the third type, which is slow, developing silently for several months before the symptoms appear. The treatment of acute perimeningitis in the beginning is the simple expectant method, and, when it is possible, operative opening of the spinal canal.

The Benefit to Ear Patients from Nasal Treatment.—From summary observations on this subject, Dr. Gradle, of Chicago, draws the following conclusions: 1. Acute suppurative inflammation of the middle ear if not treated (locally) has a tendency to become chronic, the tendency increasing with the age of the patient. 2. Chronic suppuration of the middle ear rarely heals without treatment. Neither acute nor chronic purulent otitis is influenced by nasal treatment, but the liability to relapse after their cure is decidedly lessened by the removal of naso-pharyngeal anomalies. 3. Acute catarrh of the middle ear will generally terminate in complete recovery under aural treatment, and sometimes even without it, provided there are no persistent nasal or pharyngeal lesions. But when these are present the disease is more likely to become chronic in spite of aural treatment, and in many instances can either not be cured, or if improved will speedily relapse unless the normal state of the nose and throat is restored. 4. Proliferation or adhesive disease of the middle ear is the consequence of retro-nasal catarrh, and its course is determined by the course of the disorder causing it. Aural treatment alone is practically useless in this form of trouble, while nasal treatment, if successful as far as the catarrh is concerned, will also arrest the ear-disease. The restitution of hearing, however, depends on the length of time the disease has lasted, and is often aided by ear-treatment after the cure of the retro-nasal catarrh.—*Journal of the American Medical Association.*

Recent German Surgery of Gall-stones.—Dr. Kehr out of 77 cœliotomies for gall-stones found the calculus more or less firmly fixed in the cystic duct in 26 cases. As the accepted process for their removal failed in 7 cases, he resolved upon a new (or at least unreported) procedure, namely, the direct excision of the stone from the cystic duct, with immediate suture of the wound in the duct. With this method he has had the best results. Formerly he employed the suture of the gall-bladder in the abdominal wound and waited for the pressure of bile from behind in conjunction with the diminishing swelling of the mucous membrane to force out the calculus. Now he resolves upon an immediate cystico-lithectomy if he is convinced that the stone will not be spontaneously discharged, if he feels that it is too large to pass through the contracted cystic duct, if the condition of the patient allows further operation, if the cystic duct can be freely exposed so as to render its accurate suture possible, if an immediate evacuation of the cystic duct is necessary for drainage of the biliary system. Dr. Kehr reports a series of 68 operative attacks on biliary calculi, in addition to 25 previously reported. The cases are grouped as follows: 1. Cholecystostomy, 31; with 1 death from suppurative cholangitis antedating the operation. 2. Choledochotomy, 6; with 1 death from peritonitis due to perforation of the transverse colon, the suture of the duct having held. 3. Cœliotomy and loosening of adhesions about the ductus choledochus, 1. 4. Cystectomy, 6. 5. Cholecystectomy, 5. 6. Cholecystendysis, 2; with 1 death from pneumonia, the suture of the gall-bladder being firm and there being no peritonitis. 7. Cœliotomy on account of mucous fistula, 2. 8. Exploratory cœliotomy, 3 (gastric carcinoma, 2; pancreatic carcinoma, 1). 9. Closure of biliary fistulæ, 4. 10. Opening of biliary abscesses in the abdominal wall, 2. 11. Reopening of closed biliary fistulæ, 6. No deaths occurred except as noted. Of the 3 fatal cases only 1 was directly due to operation. Kehr has arrived at the following conclusions: 1. Too few operations are performed for biliary calculi; early operation is important. 2. Many patients with gall-stones belong not to Carlsbad, but to the surgical clinic. 3. The public must be informed as to the danger of biliary lithiasis, and the physician must not delay a necessary operation. 4. The course of the sickness and the intensity of the symptoms often determine the necessity of an operation. 5. The urgency may be great, although icterus, enlargement of the liver, and tumor of the gall-bladder are absent. The pains, too, need not be typical of hepatic colic. 6. With chronic stomach trouble, for instance, gastric dilatation, especially with so-called cramps of the stomach, the possibility of gall-stones and of hernia in the linea alba must be borne in mind. Many patients are treated for gastric ulcer when they have calculi. 7. Riedel's tongue-like projection is presented in many cases of dropsy of the gall-bladder. Not seldom there is a confusion with a floating kidney of the right side. 8. Biliary colic is often a consequence of an inflammation of the gall-bladder. The accompanying icterus depends on the swelling of the mucous membrane of the biliary passages. 9. Adhesions, particularly between the gall-bladder and the pylorus, occasion attacks similar to colic, even when the stone has long ago been discharged. 10. For the removal of stones from the gall-bladder, cholecystostomy is useful; if the operation is properly performed no fistula results. 11. Adhesions must be broken up so far as possible. 12. The ideal method, with its modifications, must be rejected. 13. Total extirpation is to be thought of only when there is serious involvement of the walls of the gall-bladder, as in carcinoma, ulceration, etc. It is not indicated by a stone lodged in the bladder. In the case of a small, shrunken organ, Riedel's or Lauenstein's procedure is not available and then cystectomy is indicated. 14. Calculi of the choledochus are to be removed by incision of the duct, as previously stated. 15. Calculi of the cystic duct must, under certain conditions, be removed by direct incision. 16. Operation is often less dangerous than medicinal treatment. 17. A return has never been seen by the author. 18. Operations for gall-stones must not be performed except in surgical institutes. 19. They should be undertaken only by one experienced in abdominal work.—*Medical and Surgical Reporter.*

Abuse of the Curette: Obliteration of the Uterine Cavity.—Fritsch (*Centrabl f. Gynak.*, No. 52, 1894) reports the case of a woman, aged thirty-five, who came under his care in May, 1894. On January 31, 1892, she was normally delivered of her first living child. Child-bed proceeded without high temperature but with constant metrorrhagia. On February 24, 1892, the patient was placed under chloroform, and it appears that the practitioner used the curette freely, and to his astonishment brought away a tough piece of tissue, which he could not tear with his fingers. A tampon was applied, the metrorrhagia ceased for good, and the patient was up at the end of a week. From that time forward the menstrual period was never seen. Fritsch found the patient very healthy, free from hysteria or any other neurosis. Both ovaries could be felt; they were free from any evidence of disease. The os externum was represented by a shallow pit; it was split up, then the cervical canal, above its obliterated orifice, was found to be not quite an inch long; the finest sound failed to pass further. The uterus appeared to be reduced to an infantile condition, hardly measuring two inches and three-fourths from os externum to fundus. By aid of sound and scalpel an artificial uterine cavity was made, and kept open by a tent and gauze. After a fortnight the new cavity was com-

pletely closed. In October, 1894, the patient was examined once more ; she was found in the same condition as in May. As her general health was perfect and no operation could be likely to improve the local condition, nothing was attempted.—*British Medical Journal*, March, 1895.

Serum Treatment of Diphtheria.—Vierordt (*Deut. med. Woch.*, March 14, 1895) has treated 75 cases with Behring's serum. In 61 cases Lœffler's bacillus was found, and to this number two other cases must be added, as other children in the same house suffered from diphtheria, bacteriologically proved. From these 63 cases 8 are deducted, either as being moribund on admission or owing to some additional lesion being found after death. The mortality was then found to be fourteen per cent., as against sixty-seven to thirty-seven per cent. in the preceding six years. If the moribund cases were added the mortality would be twenty-five per cent. Among those not tracheotomized the mortality was 2.7 per cent., and among the tracheotomized forty-six per cent., the latter number not being more favorable than hitherto. Of the 24 cases admitted with the larynx intact, only 1 died, and, indeed, only one of these cases developed the barking cough. Of 5 admitted with a croupy cough and hoarseness, 1 died. Of 23 cases admitted with stridor and retraction of the soft parts, 13 were tracheotomized ; in 9 of these 23 cases the symptoms of obstruction passed off without tracheotomy in eighteen to forty-eight hours, a fact hitherto not within the author's experience. Early treatment did not always prevent a fatal issue. The cases did not appear slighter, but even, perhaps, more serious than usual (37 belonged to the severe or very severe group). No noticeable changes were seen in the membrane after the injection. The absence of spread to the larynx was remarkable. In short, a number of very severe, even desperate, cases recovered. A favorable action on the heart's action was noted. Albuminuria seemed to play a smaller part than hitherto. Paralysis of the palate was noted frequently, but no extension occurred. The author has never seen a rapid fall of temperature after the injection. A rash was noted fifteen times. A relapse occurred five times. The author concludes that no remote harmful effect was produced by the serum. Although these cases provide no absolute scientific proof, Vierordt is more and more inclined to believe in the specific action of the serum. Its use is imperative. Cases should be treated without waiting for bacteriological proof. Less than 1,000 units should be rarely used in slight cases in the young, and should be repeated in severer cases within twenty-four to forty-eight hours. The author draws attention to the rigid character of the observations which should be made upon cases treated with the serum. It must be some time before the value of the method can be absolutely proved.—*British Medical Journal.*

Ichthyol in the Treatment of Tuberculosis.—At a meeting of the Royal Academy of Turin on March 8th, Scarpa (*Gazz. degli Osped. e delle Cliniche*, March 16th) communicated the results obtained in 150 cases of pulmonary phthisis treated with ichthyol between April, 1894, and January, 1895. Having referred to the favorable results of the treatment reported by Cohn, of Hamburg, in 100 cases of the same disease, the author pointed out that from what was known of the action of ichthyol as an astringent of the vascular system, as an antiseptic, as a disinfectant of the digestive apparatus, and as an *aliment d'épargne* it was *à priori* presumable that it would be useful in phthisis. He employed the drug in the purest possible state, dissolved in the proportion of one-third in distilled water or any suitable vehicle. Of this solution he gave from 20 to 180 or 200 drops, dissolved in water, in the course of the day. The remedy was in all cases well borne. No other treatment was employed beyond attention to the hygienic environment and feeding up. Of the 150 cases 25 died ; all these were in a desperate condition before the treatment was begun, but even in them the ichthyol appeared to do good. Of the remaining cases 17 were apparently cured ; in 50 there was notable improvement ; in 32 there was some improvement ; in 28, up to the date of report, the treatment had produced no effect. The good effect of the ichthyol shows itself first in the influence which it has on the symptoms produced by the local lesions—cough, expectoration, dyspnœa—afterward on the general condition. Physical examination shows profound modifications in the lesions, especially in the circumscribed infiltrations of the early stage, but also not infrequently in those of the breaking-down stage. The author does not attempt to decide whether the ichthyol acts only by improving nutrition or also by direct action on the lesions, or by neutralizing the toxins produced by micro-organisms—both Koch's bacillus and the staphylococci, etc., which are the causes of secondary infections. He insists on the advantages which ichthyol presents over guaiacol in the treatment of tuberculosis. — *British Medical Journal.*

Diphtheria.—Fürst (*Berl. Klinik*, *British Medical Journal*, March, 1895) discusses the clinical and bacteriological early diagnosis in suspicious sore-throat. Early diagnosis is one made within twenty-four to forty-eight hours. Under the clinical diagnosis the author discusses (1) the indifferent ; (2) the suspicious stages ; and (3) the stage of the fully developed disease, and he gives at some length the symptoms belonging to these various stages. The bacteriological cannot set aside the clinical examination. The latter enables one to separate simple from other forms of angina with approximate certainty. The bacteriological examination can be effected in from twelve to twenty-four hours. The presence of the diphtheria bacillus is not absolute proof of the case being one of diphtheria, nor does its absence supply a similar proof of the absence of diphtheria. But these two statements apply only to exceptional cases. The author concludes that a satisfactory bacteriological examination is mostly impossible in private practice. There should be central stations at which such examination can be made. This bacteriological examination is, from the scientific, practical, and statistical point of view, of the greatest importance. The results of the examination must not always be waited for before the requisite treatment and isolation are adopted. Local treatment with Loeffler's iron-tolnol preparation should be practised ; a specimen of the exudation can be obtained before the application. Unfortunately, the naso-pharynx and larynx cannot always be treated in this way without special experience. Gargling should be used after the application, to prevent the burning. The specific antitoxin treatment is of use when the process is not limited to the site of invasion, and when local treatment is impossible. Its drawbacks are its uselessness (1) in septic secondary infections ; and (2) in diphtheria of the bronchi ; and (3) certain possible after-effects. Local treatment should never be neglected. The author also speaks of the bacteriological examination in those convalescent from diphtheria, and in nurses, etc., as well as of the preventive inoculation.

Cycling causes great rapidity of the heart's action, according to Sir B. W. Richardson. He says a rider while on the wheel invariably has a rapid pulse, not infrequently from one hundred and fifty to two hundred per minute.

Training Schools for Children's Nurses are to be established in connection with the Women's Lyceums, in Paris. Those who go through the training will receive a diploma, and be certificated as safe keepers of child-life.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, June 15, 1895.

THE NEED OF A LATIN REVIVAL.

CORRESPONDENCE in *The British Medical Journal* reveals an urgent need on the part of the medical profession for the purification of what Latin it already possesses, and a considerable desire to extend its use.

Taking up the latter point first, we find that Sir Edward Sieveking suggests the use by medical students and physicians of the colloquies of Erasmus. The Latin is good and easy, the subjects interesting, and the medical man might purify his latinity and relax his mind at the same time by the use of this work. There are already two magazines in Latin published for international use. Last year a Latin letter was sent to the International Medical Congress at Rome, signed by nearly a thousand medical men in India, recommending the establishment of a Latin international journal for medical and sanitary subjects. So much for this subject; as to the present condition of medical Latin, a correspondent who signs himself "Philistine" speaks words of weight and verity. "I think," he says, "the revival of Latin is a cause which would have pleased Cato but not the gods. For medical men Latin is not only dead but decomposed. Scholarship stops the nose at the putrid remnants of a so-called classical education which strew the pages of modern medical literature. To give only a few of the commoner barbarisms which can be culled from certain medical journals almost any week; we have *labiæ* intended for the plural of labium, *gummæ* as the plural of gumma, *fenestrum* for fenestra, *materia medica* intended as a neuter plural, *bronchiæ* as a plus-quam plural of bronchia, which is itself a plural; *pubis* for pubes. *Spicula*, *sputa*, and *scybala* are as often as not treated as singular forms—as indeed they are, in a different sense, to the grammarian's eye. Medicines are said to be given *per orem* in defiance of the rule as to the accusative of neuter nouns. Then there are the nouns of the fourth declension, like *meatus*, *processus*, *fœtus*, etc., to which a plural in *i* is assigned regardless of grammar. The whole tribe of Greek-derived nouns in *—ma* is treated as belonging to the first declension and the feminine gender. The dermatologists are, perhaps, the worst offenders in this particular point, and their papers swarm with such monstrosities as eczema *seborrhoica*, erythema *exudativa*, etc.; but they do not stand alone. Your gynæcologist not infrequently writes about what he calls deciduoma *maligna*, and many syphilographers take *condyloma* to be a feminine substantive. 'The vulva were inflamed,' which I noticed in a contemporary a week or two ago, may pass as a misprint, but I think it not unlikely that the author had written 'the *vulvæ*,' for this is a form which, for some inscrutable reason, is greatly affected by the average medical writer. On the other hand, 'memoranda' is often treated as a noun singular, and quite recently in a paper by a F.R.S. and F.R.C.P., I noticed 'phenomena' dealt with in a similar *supra grammaticam* fashion. But for the full bloom of barbarism the curious inquirer may be referred to the Pharmacopœia of a certain hospital for women, which might have been published as a 'Pill to Purge Melancholy' in scholars. Nor are we in this country much worse than our neighbors, for Latin of a kind that might make Priscian turn in his grave may be found in French, Italian, and Spanish medical books; and German writers on medicine add to the uncouthness of Latin style for which their scholars are notorious, a disregard of the elementary decencies of grammar which is all their own. The greatest fertility in the production of barbarism, however, is seen in the writings of our trans-Atlantic cousins, as might be expected from the superior inventiveness of that ingenious people."

We deprecate the invidious criticisms of the last paragraph. "Philistine" does not read American medical journals, or he would find their Latinity relatively pure. However, the general defects in classical learning, as shown in medical literature of to-day, must be admitted. It will not take a great deal of scholarship to correct them. And as Latin has become attached to medical literature and nomenclature beyond possibility of removal or divulsion, we suggest that medical students be drilled a little in the ancient tongue. A slighter knowledge of bones and a better pronunciation would add to the effectiveness of the profession and its repute before the world.

GOVERNMENTAL INSPECTION.

THE recent disclosures made by the New York *World* merit more than a passing notice, as the facts are admitted by the officers of the Bureau of Animal Industry, United States Department of Agriculture, point directly to a corrupt and also to incompetent inspection. Dr. Rose admits that he gave a certificate of health to a flock of sheep which he had reported had the scab disease, and that they were shipped to a foreign port by direct order of the late Secretary of Agriculture, after their true condition had been reported to headquarters at Washington. It is also claimed that this instance was but one of many of a fraudulent inspection of meat and cattle which has been going on for years in the interest of the leading packing-houses.

This is a serious matter, for it throws discredit on the whole system of government meat inspection, and has doubtless, in a great measure, determined the course of foreign nations in rejecting the introduction of cattle and dressed meats from the United States. For several years Germany and France have employed experts to keep a close watch on the inspection methods of the United States Government, and were doubtless fully

aware of the fraudulent practices carried on, without much attempt at concealment.

Secondly, it is now admitted by the Government, that all the hogs which were found infected with trichinæ, during the export inspected, amounting to two per cent. of the whole number inspected, have been thrown on the home market for consumption, instead of being boiled down in the rendering tank, as represented by the inspectors in charge.

Thirdly, it has been proved that the so-called inter-State inspection of all hogs used in the home trade has been a fraud from the word go. In large packing-houses killing as many as five thousand hogs in one day, only two inspectors were employed, whereas fifty could hardly do the work if properly done. In the face of these facts all the uninspected pork from these establishments was stamped by the Government inspector as wholesome and free from disease. No attempt was made to examine microscopically this pork, although trichinæ was the only parasite or source of disease to be feared.

It appears time that the State and City Boards of Health should take up this question of pork inspection, as it is admitted that a total of two per cent. of hogs infected with trichinæ are now found on Government inspection. The cost of inspection by the Department of Agriculture amounts to two cents per hog; but there is a great probability that a cost of one cent per hog would cover the cost of a microscopical inspection, which should be paid by those employed in placing this meat on the market.

THE COMPLICATIONS OF VACCINATION.

In the *Journal of Cutaneous and Genito-Urinary Diseases* for April, 1895, Dr. Louis Frank, of Milwaukee, Wis., gives us a very complete study of the complications of vaccination. A study of ordinary anti-vaccination literature would lead one to think that the only complications of this procedure were leprosy, syphilis, and paralysis. Dr. Frank includes leprosy and syphilis, but they occupy a most modest place in the list of complications, as established by careful and unbiassed observers.

Dr. Frank uses the classification which has been adopted by Dr. Morris and others, of the complications due to vaccination, viz.: 1. Those due to the virus itself; 2, those due to mixed inoculation, and finally, 3, the sequelæ of vaccination. Among the complications which are due to the vaccine virus itself we count nine different forms of eruptions. These include dermatitis, vaccina herpetica, erythema, and urticaria.

Dr. Frank gives a description of these various forms of skin eruptions and shows how they may be distinguished. None of them is particularly serious.

Of the complications due to mixed inoculation we find that the most common is erysipelas, while the most serious and most rare are tuberculosis, leprosy, and syphilis. Of course the anti-vaccinists make much noise over these particular affections, and consider them to be relatively frequent. Dr. Frank says that in the polemical writings of anti-vaccinists such diseases as scrofula, tuberculosis, diarrhœa, and other common causes of infantile mortality are alleged to have increased owing to vaccination. He says, however, that there is little or no reason in theory or experience to suspect that tuberculous or scrofulous infection is ever communicated by vaccination. As regards tuberculosis, only three cases are on record, and these are of doubtful value. With regard to leprosy, he says that it is not to be denied that such inoculation may be possible, but it may be said that we have at present no clear and indisputable facts proving that leprosy has been spread by means of vaccination. With regard to syphilis Dr. Frank thinks that there can be no doubt of the fact that syphilis has been communicated by vaccination, and he discusses at some length the method by which this occurs. He believes it to be clearly established that in most of the well-authenticated cases on record the conveyance of syphilis was effected by the transference of the poison from the vaccinee to the vaccinifer or from one vaccinee to the other. Some have claimed that there can be no inoculation of syphilis unless there is some of the blood of the patient mixed with the lymph. The question, however, of the transference of syphilis through the vaccine lymph becomes almost an academical one, when we consider the fact that syphilis can never be produced by vaccination with animal lymph. Numerous experiments have proved positively that syphilis is never conveyed into the genus bovinum, consequently it cannot affect the lymph from the animals of this class.

Dr. Frank has given a very interesting summary of the complications of vaccination. He shows in a general way that they are due to the use of human lymph, or to the use of impure lymph, or to imperfect methods of vaccination. A perusal of his article would convince one that while vaccination may be attended with one or more of the twenty-two complications which he analyzes, yet if pure animal lymph and vaccinè are used with care none of these complications need arise. Certainly it is absolutely possible to prevent all of the serious ones.

SERO-THERAPY OF CANCER.

The reputed success of antitoxin in the treatment of diphtheria and of tetanus has led to innumerable experiments in the serum treatment of other supposed infectious diseases. One of these experiments which, if all sources of error could be eliminated, would be most significant in its bearing upon the as yet unknown pathogenesis of an important disease, was made by Richet and Hericourt in the treatment of cancer. Two cases were experimented upon, and the results were reported to the Academy of Sciences on April 29th. On February 9th they took an osteosarcoma of the leg which had just been removed by amputation, triturated it, macerated it in water, and then injected the filtered liquid into two dogs and a sheep. There was no reaction following these injections. On the fifth, seventh, and fifteenth days blood was drawn from the animals to obtain an anti-cancerous serum.

The first case treated was that of a woman who had been operated upon in October, 1894, for the removal of a fibrosarcoma involving three of the ribs. In February, 1895, there was a return of the growth, which, at

the time of the serum experiment, was the size of a small orange. The treatment was begun March 12th, injection of 3 c.c. being made each day for forty days into the cellular tissue surrounding the tumor. On March 25th it could be plainly seen that the neoplasm was diminishing in size, and this decrease became more and more rapid until finally the tumor had completely disappeared. At the same time the patient's health was greatly improved, and she increased steadily in weight.

The second case was one that had been diagnosed as an inoperable cancer of the stomach. An injection of 4 c.c. of serum was made on April 6th, and from that date to the 24th a total amount of 60 c.c. was injected. An improvement in health was soon apparent, and a diminution in size of the tumor was evident by the fourth day of the injection. At the time the report was made no real tumor could be made out, but merely a sort of boggy feeling, indistinct and difficult to define strictly.

The diagnosis seems to have been fairly certain in the first case, and very probable in the second. Whether the results obtained were due to the action of an anti-sarcomatous serum, to that of simple canine or ovine serum independent of any antitoxin properties, to a change in local nutrition induced by the trauma, or whether they were merely coincident will probably be learned from later and more extensive experiments.

THE REPORT OF THE BRITISH COMMISSION ON TUBERCULOSIS.

Five years ago the British Parliament appointed a commission to investigate the subject of food in its relation to tuberculosis. After a long and careful investigation of this subject the commission has made its report. The members of the commission include Professor G. T. Brown and Professor Burden Sanderson, but the special expert work was done largely by Professor John McFadyan, Dr. Sydney Martin, and Dr. Sims Woodhead.

The first point investigated was the effect of feeding healthy animals with meat and milk from tuberculous animals, and this investigation was carried on by Drs. Martin and Woodhead. The flesh from tuberculous animals, freed from any obvious masses of tubercle, and milk taken from tuberculous cows, were fed to pigs, guinea pigs, and rabbits. Thirty-six per cent. of the pigs, sixteen per cent. of the guinea-pigs, and fifteen per cent. of the rabbits became tuberculous. Control animals, submitted to the same conditions of life, aside from the feeding of tuberculous food, did not become tuberculous. Experiments were made also by feeding animals with pure tuberculous matter obtained from bovine animals and from man. Each animal received but a single dose. Nearly all of nineteen animals subjected to this dosage became tuberculous. It was thus shown that the use of meat from tuberculous animals resulted in producing tuberculosis in healthy animals, and that the administration of even a single dose of pure tuberculous matter was quite sure to lead to tuberculosis.

Dr. Martin made a series of investigations in order to determine what part of the tuberculous animal was most dangerous for use as a food, and he was led to the conclusion that the muscle of an infected cow contains very little tuberculous matter, and that its consumption rarely produced tuberculosis. Even the direct inoculation of the flesh of a tuberculous cow into a healthy animal did not produce any serious results. The only danger likely to occur, therefore, in using meat from a tuberculous cow would lie in the fact that some glandular tissue might be left in the affected parts of the meat. Another danger, according to Dr. Martin, is that the butcher in cutting away tuberculous matter may use the knife again on healthy flesh, or the meat may become smeared with the caseous matter from tuberculous glands. The commissioners believe that if sufficient discrimination and care are exerted in taking meat from tuberculous cattle a great deal of it might be consumed without danger by the community.

A series of experiments was made to determine the danger to man from the milk of tuberculous cows. These experiments showed, first, that tuberculous cows with healthy udders give milk in which no tubercular bacilli can be found, and that milk from these cows inoculated into test animals does not lead to tuberculous disease. Tuberculous cows with udder disease do give milk which contains bacilli, and this milk inoculated into test animals will lead to tuberculosis.

Both Dr. Martin and Dr. Woodhead comment on the very virulent nature of milk derived from cows with tuberculous udders, and they add that butter, buttermilk, and skimmed milk obtained from the same sources also contain infective matter that is actively injurious. They conclude that no tuberculous animal of any kind should be allowed to be in a dairy herd. While the commissioners think that there is no great danger from tuberculous cows, provided the tubercle has not reached the udder, yet they strongly advise against the use of milk from any diseased animals, no matter how little infected, for the reason that the tuberculosis is so apt to spread suddenly to the udder.

Experiments were made by Dr. Woodhead upon the influence of cooking tuberculous meat and milk. Dr. Woodhead's conclusion is that ordinary roasting of tuberculous meat kills the infectious material, if any exists, upon the outer surface of the meat, but cannot be relied upon in the slightest degree to render innocuous the bacilli in the centre of the meat if any exist, especially when the joints are more than three or four pounds in weight. The most trustworthy method of cooking meat is by boiling, next comes roasting in an oven, and last, roasting before a fire. The commission seem to be agreed that boiling milk at once kills the most deadly tuberculous material. The commissioners therefore advocate in all suspected cases the sterilization of milk by raising it to boiling temperature.

The report of the commissioners does not speak very definitely upon the value of tuberculin injections in the diagnosis of tuberculosis in cattle. Dr. McFadyan states that it had led him into erroneous conclusions in about one-third of the cases (twenty-four out of seventy-five animals). The professor, however, in spite of this, adds that he has no hesitation in saying that, taking full account of its imperfection, the test is the most valuable means of detecting tuberculosis that we possess, and the commissioners add that they under-

stand that since the time of Dr. Martin's experiments the method of using tuberculin as a test has been much improved, and that it is now regarded as more trustworthy for diagnosis.

The report of the commission, of which we have above given some outline, contains, as will be seen, many facts of practical importance. The commissioners, however, owing to the long time consumed in their work, really only presented in a somewhat systematic form facts which had all individually come before the public previous to the appearance of this report.

A PROPOSED INTERNATIONAL CONGRESS OF SURGEONS.

At the recent meeting of the Congress of German Surgeons the President, Professor Gussenbauer, announced that a number of American surgeons had proposed the organization of an International Congress of Surgeons which should meet every five years, at different localities. The German Society promised its adhesion to this plan. *Le Progrès Médical*, in commenting upon it, states that the idea is an excellent one, but it fears that French surgeons will not look upon the plan with much favor, because it had its initiative in America.

We quite believe that this is possible, though it is not very creditable to the liberality of the French mind. There is no reason why a good thing should not be recognized just because of its humble source. France has had to learn much surgery from other countries. It had even to admit the originality of Sims, and it has taken other things from the despised *outre mer*. If French surgery had been more willing to learn from those living outside the sacred outlines of France, it would not be so much behind the age to-day.

News of the Week.

New York Hospital.—Dr. H. P. Loomis has been appointed Visiting Physician to the New York Hospital.

Newton Whitehead, the "specialist in female complaints," who is well known to all New York physicians through his practice of sending out cards every month, has just been tried on the charge of committing abortion. The jury disagreed, standing ten to two for conviction. The facts in his case will be now again presented to the Grand Jury by Mr. Davis, Assistant District Attorney, who will ask for another indictment containing the new legal point that this should be regarded as the second offence, inasmuch as Whitehead was convicted on June 3, 1873, of the crime of using the mails for the purpose of inducing others to commit abortion, and was sentenced on November 3d of the same year to pay a fine of $1,000 and to a term of two years in the Kings County Penitentiary.

The New Jersey State Medical Society will hold its one hundred and twenty-ninth annual meeting, at Cape May, on Tuesday and Wednesday, June 25 and 26, 1895.

The Perennial Value of a Diploma.—An absurd typographical error in an editorial with this title in our last issue might lead some unthinking reader to imagine that our esteemed Philadelphia contemporary lent its columns to advertisements of diplomas for sale. The "for sale" notice should have read, instead of address *Medical News* office, address Med., *News* office, the *News* in question being a Buffalo daily newspaper. It seems hardly necessary to make such an explanation, yet to restrain the gibes of the giddy and the foolish it must be done. We beg our valued contemporary's pardon for the error, and hope it has called forth no rebukes from well-meaning friends.

A Medical Athlete.—Our British contemporaries are all writing editorials in commendation and praise of the remarkable athletic performance of Dr. W. G. Grace. Mr. Grace is a famous cricketer, who is now in his forty-seventh year. At a recent cricket match he made the remarkable score of 288. This involves, of course, a great deal of physical strength, skill, and endurance, but we know of a good many American doctors forty-seven years old who, we are sure, could play baseball better than Mr. Grace.

The Contribution of Medical Students to a City's Health.—In a speech made at a dinner in Edinburgh recently by Dr. Clouston the statement was made that about $750,000 came to Edinburgh every year from medical students, and that the process of making doctors was therefore of much pecuniary benefit to the city. On the other hand, medical labors and discoveries had brought about a decrease in the death-rate of seven per cent. during the last twenty-five years, with a corresponding decrease in sickness. Therefore in this way also the medical men had also contributed to the health as well as the happiness of the city.

Dr. John H. McCollom is to be appointed Superintendent of the new Boston Hospital for Contagious Diseases attached to the City Hospital. Dr. McCollom is now Bacteriologist to the Board of Health.

Doctors and Incurables.—*Reynolds's Newspaper* comes out with the declaration that physicians arrange with the friends of patients suffering from an incurable disease for the death of such patients. This is a curious charge which some of our English *confrères* seem to have taken seriously. For our part, it seems to us as if nothing could be more silly or more remote from the truth.

The Chemical Composition of Oysters.—Mons. Chetin makes a report to the Académie de Médicine upon the chemical richness of oysters in bromine, iodine, fluorine, and in phosphorus. Portuguese oysters contain a gramme of organic phosphate to the dozen. Ordinary European oysters contain one-third less. This statement in regard to the phosphatic richness of oysters will be a comfort to many oyster lovers, and may in a measure offset the unpleasant reports about the capacity of the oyster for nourishing tubercle bacilli.

Monument to Charcot.—At a meeting in Paris of the committee appointed to secure funds for the purpose of erecting a monument to the late Dr. Charcot, the treasurer, Dr. Masson, stated that up to May 17th the sum of money raised was 40,000 francs. Of this

sum he stated that nearly one-half came from outside of France. The French physicians seem a trifle humiliated at the fact that foreigners have given almost as much money as their own countrymen. The committee have issued another appeal to French physicians.

The Congress of the Obstetric Society of France held a meeting in April last under the presidency of M. Gueniout. Dr. Gaulard discussed the subject of scarlet fever and the albuminuria of pregnancy. Other papers were read upon "The Causes of Puerperal Eclampsia," "The Grip in the Puerperal State," and upon "Abnormal Forms of Toxæmia in Pregnancy." M. Queirel noted that in an epidemic of influenza thirty-five puerperal women had been affected. In all cases the influenza took the pulmonary form. There were no deaths from the disease nor any serious complications produced.

The French Society of Ophthalmology held its thirteenth session in Paris, May 6th to May 9th. M. De Wecker made a report upon the use of large subconjunctival injections. He said that the injection of a drop of a solution of sublimate, one or two per cent. in strength, had no antiseptic effect. He injected an entire syringeful of solution of sublimate, 1 to 2,000, and in ulcers of the cornea his results had been very surprising. The injections were good, he said, in infectious ulcers, but of no use in other forms.

Dr. John F. Hill, of Augusta, Me., will, it is said, be the Republican candidate for governor of the State of Maine. Maine has already had one medical man as governor, and he ruled the State well. We wish Dr. Hill success.

Dr. Harold C. Ernst has been appointed Professor of Bacteriology in the Harvard Medical School.

Dr. Theobald Smith, formerly chief of the Division of Animal Pathology in the United States Department of Agriculture, has been appointed bacteriologist of the Massachusetts State Board of Health and Professor of Applied Zoölogy in Harvard.

The Legislature of the State of Rhode Island has recently passed an act for the regulation of the practice of medicine.

A New Medical Journal.—The *Canadian Medical Review* is the title of a new medical monthly published in Toronto, and edited by Dr. W. H. B. Aikins.

Dr. Maillot.—A monument to the memory of the late Dr. Maillot is to be erected, and already the sum of ten thousand francs has been collected for it.

Erratum.— In the report of the discussion of Dr. Rachford's paper by Dr. Kinnicutt, "tetany" should be substituted for "tetanus," as it stands in the MEDICAL RECORD.

Treatment by Corporation.— *The Munich Medical Weekly* says that a new danger to the welfare of medical practitioners has appeared in the shape of medical corporations which advertise to give treatment at extremely low rates. Under the advertising title of Medical Institutes, or Science Institutes, or some similar and perhaps more striking "scare-head," these organizations announce to the public that they are prepared to treat all kinds of diseases at sums much below the market rates. Naturally they also announce that they have associated with them experienced specialists with "hospital training," and a long list of titles after their names. In Munich we are told that these institutes attract people that are well-to-do and able to pay reputable medical men. Such institutions we believe exist in this city also, but we think do not form a very serious enemy to the ordinary practitioner. Most sensible people would hesitate to trust themselves to the care of an institute in which they will come in contact with medical men who can hardly be honest and who are not personally interested in the welfare of the patient.

Dr. J. Marshall Hawkes, of this city, died on Sunday, May 26, 1895, of osteitis of the mastoid bone, following an acute attack of purulent middle ear inflammation. He was born in Gorham, Mass., in October, 1847. He served a year and a half in the late war in the Fourth Maine Battery; later he entered Dartmouth College, New Hampshire, where he first began the study of medicine. He was graduated from the College of Physicians and Surgeons in this city in 1890.

The Surgery of the Present Day is distinguishing itself from the surgery of the past few decades, not so much in the perfecting of the mechanical art as in the development of surgical pathology; and the surgeon of the future, if he would embellish himself with something extrinsic to his art, will choose to study the histogenesis of sarcoma in preference to the branches of the external circumflex division of the profunda femoris artery. Surgical pathology is teaching the surgeon that carcinoma is not a lump to cut off, but that it is an insidious, spreading disease, and that it more closely resembles erysipelas than it resembles a wart. With the growth of surgical pathology in this country, American surgery is in less danger of sustaining the set-back which it received at Washington a few years ago, when one of its champions announced before a great meeting of surgeons that he opened the axilla in breast cases only when he could feel through the skin that the glands were enlarged. It is one of the functions of such works as that which lies before us to encourage in the surgeon the use of the "microscopic eye" as an aid to the finger.—*Annals of Surgery.*

Payment for Information Regarding Medical Examiners.—The *Texas Medical Journal* for April, 1895, in speaking of the insurance controversy, makes the following comments: "The *Columbus Medical Journal* has taken up the position of the *Texas Medical Journal*, the *Texas Sanitarian*, and the *California Southern Practitioner* as to the insurance companies paying physicians for information when referred to by applicants for position as medical examiner, and the editor and Medical Director Curtis, of the Equitable, are engaged in a bitter controversy. The *Columbus Medical Journal* is right. It has ceased to be a question here, and the Austin physicians send in a bill for $5 every time a request is made for information about an applicant, and for our part we always get our money." The *Texas Medical Journal* adds that the Bankers' Alliance of Los Angeles, Cal., has adopted the plan of paying for services rendered.

The Index Medicus has been discontinued.

Society Reports.

ASSOCIATION OF AMERICAN PHYSICIANS.

Tenth Annual Meeting, held at the Army Medical Museum and Library in Washington, D. C., May 30 and 31, 1895.

(Continued from page 721.)

Second Day, Friday, May 31st.

Diphtheria Antitoxin.—The discussion was opened by Dr. William H. Welch, of Baltimore. The decision as to the good of this remedy is in the hands of the clinicians and not the bacteriologists, as many suppose. There are various theories as to the action of antitoxin. Gunzemann holds that its use does not rest on a scientific basis. Of course it must be admitted that the Klebs-Loeffler bacillus is the cause of diphtheria. His arguments would hold equally well against other diseases. The results of experiments are the most striking, but we know more of tetanus antitoxin. We cannot always argue from animals to human beings in our experiments. The antitoxin of tetanus has a cumulative action that the diphtheria has not, and often the diphtheria antitoxin is used too late to help. We do not know how it acts, but we do know its therapeutic results, and this is also true of other diseases. This should not prevent us from using it. There are two prominent theories, the chemical and the vital theory; that is, the antitoxin either acts as an antidote to the toxin and is a chemical change, or it produces some change in the cells to make them immune. The vital theory seems to have the most followers. This method of treatment does not prevent post-diphtheritic paralyses. They are just as frequent whether the antitoxin be used or not.

This paralysis depends upon the action of the toxins, and is against the chemical and speaks for the vital theory. There is a quantitative relation between the toxin and the antitoxin. There is no means of knowing how much toxin is in the blood, and how much antitoxin should be given. We may give too little. Whether it exerts a direct specific action on the membrane is hard to say. Some believe it does, and others do not believe this. In some cases it may, and in others not. The benefits of this treatment are very doubtful when the antitoxin is introduced after the third day. This has been shown in the case of animals, and Behring holds to this point. We are not to expect brilliant results unless we know it is diphtheria, and the specific bacillus must have been demonstrated. Thus we may include cases not found before. It is in healthy throats, mild anginas. Now if these very mild cases not to be recognized clinically are to be put down as diphtheria, the prognosis will be more favorable and this will influence our statistics. On the other hand, there are certain cases of pseudo-membranous inflammation which are like diphtheria, but which are not due to the Klebs-Loeffler bacillus. All these cases are put down as diphtheria, and this also affects the statistics. As regards the prognosis of these cases which look like diphtheria, and which are not, statistics differ. And here is why a large number of statistics are needed from State boards of health and hospitals, which will give us an idea on the use of this remedy. Again, take, for instance, the manner of examining throats and cultures from the throats. These examinations are made in a routine manner, hurriedly, by inexperienced men, and the difficulty of finding the Klebs-Loeffler bacillus, and we may say that thirty to forty per cent. are not recognized, while others say five to ten per cent. Then again in our experiments we must remember that the diphtheria of animals differs from the diphtheria of human beings. In so many cases we have not a pure culture of the specific bacillus in the throat, but a coccus is there, besides the streptococcus of septicæmia, the pneumococcus. Then the mechanical obstruction in the larynx must be considered. These help to make a case unfavorable. As to the direct effects, they are various. It is probably manifest but not different from those that may occur in the natural cure of the disease. Indeed the cure is a natural cure. The natural cure is by antitoxin, and this method is only a hastening of this cure. The statistical results are at the present time elaborate. He has a small number. In France, from June to December, 1894, there were twenty-seven hundred cases, with sixteen per cent. mortality. In Austria, outside of Vienna, a large number of cases, with forty per cent. mortality. Other observers have collected statistics to show that the mortality had been reduced from fifty and forty per cent. to ten per cent. after the use of the antitoxin. Now what are the conclusions to be drawn from these statistics? There are three classes of opinions caused by them. According to one class they prove nothing, to another they leave the matter entirely in doubt, neither for nor against it. Others believe the statistics prove nothing or everything. They include a large number of light cases. Mild cases are called diphtheria. The agitation of this subject in the public press leads the patient to send his children to be examined, and thus if a case is discovered the treatment is begun earlier. These cases ought to be classified so that we can tell the number of each kind. Then there is the question of the effect of the treatment on the false membrane and the complicated cases in which the larynx and pharynx are involved. These are all arguments in favor of this treatment. But it is argued against this that the present attacks are milder and the mortality is lower than in ordinary seasons. According to Bollinger, the mortality is higher in Vienna and lower in Berlin. It is claimed that treatment is begun early according to the directions of the boards of health, and when it is begun on the first or second day the chances are good, and the case does not end fatally. In some cases the antitoxin has no effect at all, and the case dies or does not improve. In this case the cells fail to respond for some unknown reason, and the antitoxin fails. There are very few cases of this kind where no reaction at all is obtained. Then there may be other conditions of the patient which may affect the action of the serum. But whatever we may say, it certainly looks like a genuine cure. Of course there are improvements yet to be made. Some ideas are also to be gleaned from the general opinions and the clinical impressions of such men as Baginsky, Widerhofer, and others, as to how they are personally impressed by this treatment, and what they learn at the bedside. This is a new kind of argument. Kassowitz is opposed to this treatment. He made two hundred autopsies and claimed that as much could be done with the bichloride of mercury as with antitoxin. There are some injurious effects from antitoxin. There is some evidence that it causes albuminuria, and this calls attention to the careful examination of the urine in diphtheria. Albumin has been found in from eighty-three to seventy-six per cent. of all cases treated. Arguments as to the injurious effects of the serum should be based on the fact whether the injections are subcutaneous or intravenous. Then there are the skin eruptions, etc., which are occasional ill effects of the serum. Still these are not permanent, and they cannot outweigh the benefits. On the whole there seem to be much more advantages than disadvantages in using this treatment, which even the most sceptical should admit. All agree that the best effects are obtained early in the disease. Whatever injurious effects are felt are not permanent, and they cannot compare with the benefits. There are certain cases which cannot respond to treatment. It will take a long time before final judgment can be obtained.

Preparation of Antitoxin, by Dr. H. C. Ernst, of

Boston, was read by title, owing to the absence of the author.

Dr. Mason, of Boston, reported on a number of cases treated in the Boston City Hospital. He quoted a large amount of statistics showing the reduction in mortality since the use of antitoxin. There are many factors to be considered in this reduction of mortality. There have recently been appointed a number of school inspectors who have examined the throats and noses of the schoole-hildren, and in many cases diphtheria has been discovered in its early stages and has been treated successfully. The moral effects in the wards, too, are very noticeable. There are fewer very ill children, the attendants are not afraid, and the whole place has a more cheerful appearance, which has a moral effect on all those near by, and may in a small way influence the mortality. The number of light cases may be greater than before, but usually in hospital the cases are not seen before the third day at least, and here the chances for cure are much smaller. He was inclined to speak favorably of the treatment, although on the whole it was perhaps a little early to give a decided opinion.

Dr. A. Jacobi was inclined to give a favorable opinion, but the small numbers are not sufficient from which to draw deductions. We do not want hundreds but thousands of cases, in different cities. Otherwise there have been seasons when other treatment has been just as efficacious as this. In one set of 40 cases, of which he knew, 39 got well, and in some years he found that the mercury treatment did as well as the antitoxin does now, and some have preferred to keep up with the bichloride treatment. The bichloride treatment is very useful in paralysis, and this has to be taken into account. He used the bichloride and other treatment even when he used the antitoxin. This may not be scientific, but he wished to save as many patients as possible. As to albuminuria, it is a very prominent symptom, but it had been found not to occur as frequently in patients who had been treated with antitoxin as with the others. The nephrites are not so marked after antitoxin. Baginsky has seen a large number of cases, and he says the number of operations is less since the use of antitoxin. He wished to place himself on record as a heretic. The clinicians are too much in the hands of the bacteriologists. It was well known years ago that diphtheria was caused by a bacillus. The Klebs-Loeffler bacillus is rarely found alone in the membrane, but with the streptococcus, and we cannot say whether the disease is a poison of the streptococcus or the Klebs-Loeffler bacillus. We do not know what the toxin or toxins of diphtheria are, and we have mild cases and severe cases, and one kind can come from the other. He was not prepared to accept the postulate that the diagnosis rested on the discovery of an organism, and it is only the genuine Klebs-Loeffler cases that are amenable to the antitoxin treatment.

Dr. John S. Billings, of Washington, spoke of the use of statistics, and said that the question of the utility of statistics rested only on a large number of cases continued over a long space of time. At present the statistics on this question were not sufficient to give absolute and positive results. It is difficult to compare present finding with past, and it would be bad for hygiene if reliance were placed on antitoxin alone. There are various things to be considered, and the mortality in different localities is an important question.

Dr. Mason, of Boston, said it was impossible to give all the points to which Dr. Billings referred. The comparison can only be made with a series of cases from the corresponding seasons of another year. Also the method of treatment in vogue at any particular time must also be taken into account.

Dr. A. C. Abbott, of Philadelphia, said that clinicians depended very much on the bacteriologists for help. Until the bacteriologist found out the cause of many diseases the etiology of such diseases as diphtheria, tuberculosis, etc., was in a very chaotic state, the distinction was uncertain and the treatment unreliable. The clinicians can distinguish mild from severe cases, but the mild cases are often not recognized at all until the bacteriologist adds his help. The bacteriologist can tell which case is diphtheria and which is not, and that with certainty.

Dr. George M. Sternberg, Surgeon-General U. S. A., said there was much scepticism on the use of the lower animals for experimentation and comparison, because of the partial failure of tuberculin.

Dr. F. H. Williams, of Boston, had used antitoxin since last September, and he noted marked improvement in many of the severe cases where it was used early enough in the first twenty-four to forty-eight hours after the administration of the remedy. In the first day the membrane loosens rapidly and improvement is marked. He related a case. Now and then there are cases in which the convalescence is less rapid than without the antitoxin, and he has noticed this in a few cases. He showed the syringe which he used. It is made of glass, with asbestos filling, and may be sterilized by boiling, without injury. A rubber tube between the syringe and the needle is flexible to prevent the needle from being broken off in a restless child. All things being equal the prognosis is more certain when there are no bacteria present.

Dr. William Osler, of Baltimore, reported a number of cases seen in the hospital in which improvement was nearly always marked. In four cases the Klebs-Loeffler bacillus was absent.

Purpura Hæmorrhagica Rheumatica.—Dr. D. W. Prentiss, of Washington, D. C., reported a case of this trouble, also called peliosis rheumatica and morbus maculosus Werlhofii. He showed this case in 1890 when the boy was thirteen years of age. Now a nephritis developed after the hemorrhages. The eyesight is gradually failing, and there are some degenerative changes in the yellow spot. He still follows his trade of a carpenter. An analysis of the urine showed it to be clear, of an amber color, specific gravity 1.005, amount about two quarts, acid, twenty-five per cent. of albumin; urea is one-third of one per cent., which is remarkably low. The hypobromite method was used.

Dr. William Osler said it was doubtful whether all these cases should be classed as purpura hemorrhagica. The first proper classification was made by Henoch, of Berlin. He spoke first of the recurrences; they recur year by year. Second, there are marked gastro-intestinal crises, which may occur without any other symptom. Third, arthritis, which is not always present but may occur, is one. Fourth, the hemorrhages which start under the skin, erythema multiforme, simple œdema, purpura, hemorrhages from the mucous surfaces with this in some cases of acute nephritis. He reported one fatal case. The literature of this disease is very sparse in English, but it is to be found in Henoch's "Festschrift."

Dr. Charles G. Stockton, of Buffalo, referred to a case with hemorrhages from the retina and for the past five years severe gastric crises. There was also anæmia, but no albuminuria.

Dr. Osler said he had notes of eight cases. He recalled no case of chronic nephritis. In Henoch's "Festschrift" there is no American and but one English author mentioned. The disease is not uncommon.

Dr. Prentiss asked for suggestions for the treatment. One physician had proposed phosphorus, and he had used it with decided benefit.

A Case of Madura Foot (Mycetoma Pedis).—This was a case reported by Dr. J. G. Adami, of Montreal. It was a man who had lived all his life in America, and it was probably the first undoubted case reported on this continent. It began as a small spot on the foot and gradually spread, and a microscopical examination

of the part of the tissue in the affected foot showed it to be much like actinomycosis. The limb was amputated.

Gonorrhœal Rheumatism—Clinical Observations.—This was a report of several cases by Dr. William P. Northrup, of New York. The first case was a woman who gave birth to a child who, a few days later, had a purulent ophthalmia. The woman shortly after developed an arthritis in one knee and later she had erysipelas. In another case the elbow was affected; in the third case the elbow, the fourth case also the elbow, and the fifth case the knee. It was noticeable that all his cases were those of monoarthritis; there had been no suppuration, in all there was exquisite pain and the joint was exceedingly sensitive; there was little swelling, and recovery without suppuration. He found on looking up the literature that most of the cases were not monoarthritic. In all his cases he found the following characteristics: One joint was affected, either the elbow or knee; the swelling was fusiform, indicating a periarthritic lesion with synovial effusion, probably serous, which was soon absorbed, leaving no adhesions. There was exquisite sensitiveness, with little local heat and little fever. The course and duration of the trouble were usually about four weeks, with recovery with a perfect joint.

Dr. William H. Welch, of Baltimore, said there was no question but that there were distinct types of gonorrhœal arthritis. The exudate formed is serous, and there is no pus and no suppurating causes present. Dr. Halsted had opened a number of joints at the Johns Hopkins Hospital, and found the contents serous. In the early days of surgery we had very little success in this direction, but now we have improvements. At present we have been more successful in cultivating the gonococcus. He showed a culture from an exudate in suppuration of the sheath of a tendon of a muscle. Many denied this disease. There was a diffuse swelling around the ankle-joint, with involvement of the tissues and the sheaths of the tendons with pus. Cover-slips were made from the pus and the diplococcus was found, and they were decolorized by the Gram method. It is interesting to note that Dr. Flexner had found accidentally a good culture medium for this organism; it is an extract made from fœtal pigs. As regards the interpretation of these lesions, it is not possible to say with exactitude that post mortem it is a case of gonorrhœal arthritis. Dr. Halsted has noticed the existence of hemorrhages in these joints, but this alone will not aid us. He related the case of a woman who had been three weeks outside of the hospital and two weeks in. She had a marked endocarditis with chills, irregular temperature, at times running high, petechiæ in the skin. She had anæmia, a presystolic and systolic murmur. The diagnosis was made at the bedside. At the autopsy there were found vegetations on the auricular surface of the mitral valve. There were evidences of thrombosis. There was hypertrophy of the left auricle and right ventricle. The spleen was large and hard. The blood was withdrawn a few days before death and mixed with agar, and a culture was made which showed a large number of whitish-gray cultures, which were the gonococci. Thus during life the gonococcus was present in the blood, causing a general septicæmia and a genuine endocarditis. This is the first instance, as far as he knows, in which the blood was withdrawn and used as a medium in this way.

Dr. F. C. Shattuck, of Boston, said that the general impression is that gonorrhœal synovitis or arthritis was very apt to be monoarticular. That was his impression, and it was the general impression, but when he went to look into the subject he found that out of 64 cases collected by himself, it was monoarticular in 6 only, and the rest were two or more joints. Dr. Welch must have overlooked some investigations of Dr. Hughes, who had made cultures from the blood and gave the disease to a bitch. He had seen two cases of malignant endocarditis following gonorrhœa, and in one that came to autopsy there was found an old endocarditis. He did not know whether the endocarditis was due to gonorrhœa or to the organisms of suppuration. He related several cases bearing on this point.

Dr. Charles Cary, of Buffalo, related two cases, in one of which the young man had the disease in his shoulder and knees. He had a spot of pain on the dorsum of the foot, and it developed into a general phlebitis involving the femoral vein.

Dr. Mason said, at the request of Dr. Northrup he had collected some cases of this trouble in the Boston City Hospital. In his cases the effusion was serous, with one exception. In one case it was explored and pus had lately formed. The great difficulty in collecting these cases about the diagnosis was the small number of autopsies. There were only five post mortems in all these cases. There were two deaths in one hundred and twenty cases. In a few instances the blood-serum was examined, but it was usually sterile.

Dr. J. P. C. Griffith, of Philadelphia, said he had also collected some cases for Dr. Northrup.

Dr. J. G. Adami, of Montreal, mentioned a case that occurred in his laboratory. The fluid was drawn from the joint and no culture could be made, but when mixed with agar the culture was made.

Dr. J. West Roosevelt, of New York, said that out of ten cases which he had seen six had one joint affected; two, two or more joints. In these cases there was no successful result from cultures, but the cases were undoubtedly gonorrhœa. Cases which tend to become chronic are not usually amenable to treatment. One would think that if no gonococcus could be found the case would not be considered gonorrhœal arthritis.

Dr. Osler said that Dr. Flexner had collected out of twenty-seven cases five which were interesting. In four there was a sero-hemorrhagic fluid and in one only was there pus. These statistics should be recorded as a valuable addition to the literature of the subject.

Dr. Northrup said the question came back to the point, is there a characteristic lesion? The various symptoms are not all characteristic. He related another case.

Hyperthermy up to 148° F.—This was a case reported by Dr. A. Jacobi, of New York, of a man whose temperature ran up to this incredible height. He related cases similar to this and referred to hysterical temperatures. This man had taken a great interest in his case and always asked about the notes made from day to day, and he finally ran away from hospital and all traces of him were lost. He came in for an injury.

Dr. William H. Welch said that he failed to mention the well-known case of Galbraith, of Omaha, where the temperature is said to have gone up to 171° F. for a few hours. He is said at first to have considered the case ridiculous and would have nothing to do with it, but later he took a great interest in it. Like Dr. Jacobi he broke thermometer after thermometer, and finally had one especially made. These are mysterious questions, and we do not understand them. It seems to be a physical impossibility to have such a high temperature and live.

Dr. F. C. Shattuck, of Boston, said he had a case which he was keeping to hitch on to some such paper as this. This is the first case in a male. He had a chart where the temperature went up to 117° F. He was sure it was a fraud, but others saw it with him and it kept up there for an hour.

Dr. George Dock, of Ann Arbor, said it would be interesting to know the temperature of the urine, and asked if he had taken it.

Dr. M. H. Fussell, of Philadelphia, reported a malingerer who had a high temperature in one part of the body and a low one in another.

Dr. A. Jacobi said he had neglected to take the temperature of the urine, but had taken the temperature

in the mouth, axilla, popliteal space, rectum, and urethra before many witnesses and with many thermometers.

Some Observations on the Spleen and Marrow in Leukæmia.—This was the subject of a paper by Dr. J. Guitéras, of Philadelphia. It was on the formation of the red blood-cells in the spleen and marrow. He called attention to the peculiar mode of cytogenesis as illustrated in the capsule of the spleen. It is from these organs that erythroblast and cells are formed. He related cases illustrative of his point and gave the post-mortem results.

A Comfortable Way of Using Cold in Fevers.—This was a paper by Dr. F. H. Williams, of Boston. His idea was that, rather than put a patient in a tub, it is easier and safer to wrap the body with ordinary surgical gauze and then sprinkle it with an ordinary syringe. His experiments were carried on with a bottle which he filled with water at 104° F., wrapped it with gauze, and then sprinkling the gauze with very little water he reduced the temperature in half an hour 20° to 30°. Several sprinklings are necessary. Two palm-leaf fans keep the patient cooler and reduce the temperature better than an electric fan. He tried ninety-five per cent. alcohol instead of water, but found it had little advantage over the water and was much more expensive. The shock of cold water is too great for the patient's good, while this gradual sprinkling with water which is at first tepid and later cold gradually brings down the temperature without producing a shock. He liked it better than the sponge-bath.

Goitre in Michigan.—This was the subject of a paper by Dr. George Dock, of Ann Arbor. He referred to the prevalence of goitre in his neighborhood in man and in animals. He had tried to excite some interest in this question, and had corresponded with physicians throughout Michigan and tried to arouse some sentiment about it. The disease is sometimes mild and sometimes severe. It was usually supposed to be caused by the drinking-water, and this was the cause assigned to it in Alpine regions, where there is much melting snow and glacier ice. But there were no such conditions in Michigan.

The water cause has lost ground, and now it is believed that the cause is either a microbe or a toxin. He has seen the disease in horses. It is not usually of large size in his cases. He has tried the dried thyroid treatment and is favorably inclined to it, although his cases are so few that he hesitates to record them.

Dr. Henry M. Hurd, of Baltimore, said that Dr. Clark told him that there was an increase of the disease in the asylum at Kingston, Ontario, after the patient came there.

Dr. Osler said that it was remarkable how the disease had disappeared from regions where it had formerly been prevalent.

Displacements of the Liver.—This was the subject of a paper by Dr. J. E. Graham, of Toronto. After a brief account of the literature he recorded three cases. The liver is movable. It may be floating liver or simply a displacement. The former is more common. More cases occur than are recorded, but it is less frequent than floating kidney. The ligaments are usually strong enough in health to suspend the liver without the abdominal walls. In child-bearing it is lower. He has had three cases. The etiology is pregnancy at full term, pendulous abdomen, hepar pendens, and stretching of the ligaments. There may be also turning and twisting of the suspensory ligaments. Tight-lacing was found to be a probable cause in 6 out of 55 cases. It is not easy to displace the inferior vena cava, but when the liver is lower the vena cava becomes gradually displaced. As to treatment, sixteen cases were relieved by abdominal support, and in one case a bandage could not be worn, as it increased the pain and tenderness. A support is often of benefit. Four operations are reported. Seventy cases in all were recorded.

Carcinoma of the Liver with Cirrhosis.—This was a paper by Dr. M. H. Fussell, of Philadelphia. He reviewed the literature and said there were few references to it in any language and none in English. He reported two cases, in which he considered the relations of the cirrhosis to the cancerous growth, and spoke of the origin of the cancer cells, discussing the question whether they were from the hepatic cells or intertubular ducts.

Milk as a Morbific and Infective Agent.—This was a paper by Dr. S. C. Busey in collaboration with Dr. George M. Kober, of Washington, D. C. It gave tables of 134 epidemics of typhoid fever, 73 scarlet fever, and 27 diphtheria cases due to milk infection. It was an exceedingly elaborate and carefully prepared paper, which showed that milk had been the means of transmitting disease to infants, children, and others, and the various ways by which it was possible for disease to be carried in this way.

Forcible Artificial Respiration—Fell-O'Dwyer's Apparatus—Cases.—This was a paper by Dr. William P. Northrup, of New York, who exhibited an apparatus for forcible respiration, and his paper contained an account of cases in which artificial respiration was maintained four, twelve, and twenty-five hours, in fracture of the skull, with operation, and opium poisoning, etc.

On the Direct Faradization of the Mucous Membranes of the Stomach and the Intestines of Animals, as Dogs, Cats, and Rabbits.—This was the subject of a very exhaustive paper by Dr. S. J. Meltzer, of New York, in which he elicited the fact that, against all clinical expectations, the experiments on animals revealed the surprising but not practical fact that, neither the stomach nor the intestines can be brought to contraction by faradization of their mucous membranes. Neither can the stomach be brought to contraction by application of one of the electrodes on the mucous membrane and the other direct on the muscular sheath of the stomach. The application of one electrode on the intestines and the introduction of the other into the rectum does not produce any contraction of the intestines, but kills the animal sometimes.

AMERICAN GYNECOLOGICAL SOCIETY.

Twentieth Annual Meeting, held in Baltimore, May 28 29, and 30, 1895.

Matthew D. Mann, M.D., of Buffalo, President.

First Day, Tuesday, May 28th.

(Continued from page 723.)

Abdominal Section for Puerperal Septicæmia.—Dr. J. M. Baldy, of Philadelphia, read the paper. The author had had one experience last February, in which, on account of the presence of pus in the abdomen in a case of puerperal septicæmia, he removed the uterus some time after the delivery and the patient recovered. He then discussed the propriety of performing hysterectomy in cases of puerperal septicæmia in general. The indications were clear where pus was present, but there were cases in which pus had not formed and the indications for operative treatment were not clear. The question was also more difficult in cases of infective lymphangitis, and it could be stated at once that a large number of cases in which suppuration had not taken place could be excluded from the category of treatment by abdominal section. But even in other cases it might be contended that it would be useless on account of the infection having already become general, but this we did not know. As a rule, if anything was to be accomplished, it must be done during the first

week or two, and each case had to govern itself as to the propriety of any given procedure. After all was said, the distinction would have to be a clinical one. It must be admitted that the field for hysterectomy in puerperal cases was not a large one. The paper contained a list of the cases operated upon in America, nineteen in number, seven with recovery. While it was possible that some of the latter might have recovered without operation, the reports indicated quite the reverse.

Dr. Fernand Henrotin, of Chicago, had understood the author to say that the abdomen could be opened and drained with gauze as safely through the abdomen as the vagina. To that statement he would take absolute and decided exception. Regarding the propriety of taking away the uterus in some of these cases, it was positively his opinion that the method was proper under certain circumstances, and he would allow that in doubtful cases it was very proper to open the abdomen and try to reach the seat of the disease so as to be able to judge whether it was possible to do more conservative work than to remove the uterus. He claimed, however, that much conservative work could be done in these cases, as would be shown in his paper to be read the next day, and that vaginal incision and drainage practised early would obviate the development of abscesses and the more advanced septic state. The question of the method of operating, whether by the vagina or abdomen, after the disease had become well advanced, would be discussed later. His only object in rising on this occasion was to impress the necessity of trying to cure these patients without such severe and dangerous operative procedure or before the necessity for these had arisen.

Dr. W. Gill Wylie, of New York, said that his work had not been so much in the obstetrical line, yet he wished to direct attention to the fact that it was possible to cure puerperal septicæmia by a very simple procedure, namely, clearing out and washing the uterus. He would not undertake an operation until he had first tested the efficacy of this simple procedure, for while it would fail where the disease had passed beyond the uterus, and the woman had become thoroughly septic, yet we were unable clinically to state just when the latter stage had arrived. He had by this method, within the last year, cured two young women completely, after the cases had been given up by others as hopeless. Dr. Wylie said that he believed as much as anybody in opening the belly in this class of cases, but not before trying washing out the uterus. His method of doing this was different from the common practice, and would be described in a paper which he would read the next day.

Dr. A. F. Currier, of New York, would narrow the discussion down to those cases in which the inflammation was limited to the uterus and adnexa. According to his experience the removal of these organs after the development of advanced septic disease following the puerperium was not likely to prove successful. There was a class of cases in which the products of inflammation were extra-peritoneal which were quite amenable to operation.

Dr. Charles P. Noble, of Philadelphia, thought there was a practical point which should be brought out sharply, namely, the difference between early and late cases. There were cases in which one found a collection of pus within the tubes or elsewhere three to ten weeks after labor. These were very different from those cases of sepsis seen only a week after labor, and their treatment was, according to well-known surgical rules. He had removed the uterus in a case of early sepsis not cured by treatment directed to the interior of the organ, and the result had been what he had expected, death.

Dr. H. C. Coe, of New York, cited a case operated upon by him two weeks ago which seemed to possess all the conditions to result successfully. The pulse was 110; temperature, 100° F. He had operated upon the fifth day, found a condition that would be characterized anatomically as the congestive stage of peritonitis, a small amount of serous fluid in the abdominal cavity, no adhesions, no organized lymph, the tubes and ovaries practically free. There was acute salpingitis and acute abscess of both ovaries, which he removed. Not wishing to complicate the case by shock he left the uterus, the cavity was washed out thoroughly and drained through the vagina. The patient died within twelve hours, of collapse. The case had been a very discouraging one to him, and he must agree with those who characterized abdominal section for puerperal septicæmia as purely experimental.

Dr. Lapthorne Smith, of Montreal, called attention to the fact that in puerperal fever the uterus might become bent upon itself and pus collect in its cavity, which without special attention would remain as an abscess and lead to general puerperal peritonitis and death. At hysterectomies, etc., upon septic cases he had observed pouring out of septic matter from the numerous little vessels which were cut across, and suggested that the parts be wired off to prevent the escape of septic matter.

The Relations of Lithæmia to Diseases of the Pelvic Organs in Women was the title of the President's Address. In opening his address Dr. Matthew D. Mann, of Buffalo, thanked the members for the honor conferred upon him, expressed regret that more interest was not taken in obstetrical work in the Society, stated that the method of teaching obstetrics in our medical schools was faulty, alluded to the great loss which the Society had sustained in the death of Dr. Goodell, and then passed to the main subject of his address, "The Relations of Lithæmia to Diseases of the Pelvic Organs in Women" It had been frequently noted that the trend of modern gynecology was largely toward the surgical side. It must be admitted that by resorting to the knife, except in cases of injuries, we confess to a certain extent our defeat. He would try to throw a little light upon the origin of certain rather obscure diseases of the pelvic organs in which the particular trouble was of minor importance or secondary to certain general conditions. No discussion of this subject would be complete which did not include the urinary and alimentary organs as well as the genital. To show how these organs may be related by their position alone, take the case of gonorrhœa; not only might this disease travel up the urinary track to the kidneys, but the rectum might become infected. The President then enumerated some of the symptoms met with in which the trouble seemed to depend upon the close interdependence of function and disease in the nearly related pelvic organs. The symptoms complained of were often vague and difficult to describe. The patient told of pains and aches in various places, many of which were called reflexes.

There were menstrual disturbances, vaginal discharge, backaches and frontaches, troubles of bladder and rectum, insomnia, dyspepsia, coated tongue, dry skin, depressed spirits, headache, nervousness. Physical examination often showed no serious lesions in the pelvic organs. The urine was almost always below the normal in quantity. In twenty consecutive cases taken at random he had found the average amount of urine passed in twenty-four hours, fifteen ounces, or less than one-third the normal. This scanty urine was always acid, usually of excessive degree, and generally contained excess of uric acid. Even when the quantity was below normal, the specific gravity was seldom high, showing a deficiency in solids excreted. The President had come to look upon this condition of urinary insufficiency in its relation to pelvic diseases as of the utmost importance. Differ as we might as to the exact nature of the poison contained in the urine, there could be no doubt that the urine as a whole was toxic. The retention in the system of the toxic agent which should be

eliminated by the kidneys, could not but have a deleterious effect. Another fluid whose examination must not be neglected was the blood. Herter had said that he had been surprised to find how many neurasthenics, whom there was no reason to think were anæmics, had shown a decidedly reduced proportion of hæmoglobin. For want of a better term Dr. Mann called the condition lithæmia, which he would define as follows: "A distinct disturbance of nutrition of a certain type in which there are peculiar tendencies, one of these tendencies being the output of excessive amount of uric acid. As this disturbance of nutrition inclines to continue and to recur in the individual, we may properly apply to it the term diathesis. Hence the term uric-acid diathesis." To simply treat such cases as though they were uterine or ovarian, pure and simple, was utterly useless, and yet the uterus and ovaries might need treatment even of a radical nature. Supposing, for example, that the trouble started in the stomach, perhaps from some error in diet or nervous strain, the President traced the effects which might be thus produced upon the digestion, upon the hepatic and portal circulation, causing pelvic congestion, this leading to catarrh of the uterus, this again perhaps to purulent inflammation, and so on. Imperfect metabolism of the food-products resulted in poisonous substances in the system, and owing to imperfect action of skin, kidneys, liver, and bowels, the poisons were not excreted. This led to many nervous derangements. So a vicious circle was established, always reproducing and intensifying the morbid condition. Further attention was called to the irritating effects of the urine in producing bladder symptoms. Exactly what was the irritating substance of the urine had not yet been determined. Whether excessive acidity was the only thing, was not certain, but be this as it might clinical observation went to prove that neutralization of this acidity by alkalies overcame to a certain extent the irritative qualities. The rectum might become involved in pathological change by interference with the portal circulation, by undigested food, backward displacement of the uterus, and the prominent symptom was constipation. The original source of disturbance, instead of being in the stomach, might be in the uterus, as laceration of the cervix, a displacement, or endometritis. If we sought for special causes we would find them on every hand—climatic, dietetic, social, and faulty methods of dress. The latter was dwelt upon at a considerable length. Tight-lacing was not the only source of mischief, for snug-fitting dresses were also capable of producing displacement of both uterus and all the abdominal viscera. The stomach and large intestine, especially, were often found displaced. Comparative observation had shown that these displacements were much more common in women than men. More recent observations had shown that respiration was performed the same in women as in men. The present mode of dress among civilized nations, changing as it did so important a function as respiration, must have a marked influence on the contents of the abdominal cavity. If one doubted the prevalence of waist constriction let him apply the following test: Put a tape-measure around the waist outside of the clothing and note the difference between forcible expiration and inspiration. More than one-half of the women would be found to show no change at all, about one-third would move the tape one-fourth of an inch, while one in twenty-five, perhaps, would move it nearly an inch. Men could easily move it two or three inches. "A campaign of education" was sorely needed in the matter of dress reform for women.

Renal Insufficiency in Gynecological Cases.—Dr. James H. Etheridge, of Chicago, was afraid, in view of the furor for operative gynecology, that a paper on the subject of which he was about to treat would meet with a cold reception. In connection with dispensary service his attention had been struck by the large number of gynecological patients complaining of general symptoms. He had analyzed these symptoms, and would speak of those relating to the kidneys present in one hundred cases without distinct signs of renal disease.

The amount of the solids voided in the urine in health each day varied, according to the weight of the individual, from five hundred grains for a person of ninety pounds to eleven hundred grains for one weighing one hundred and eighty pounds. Patients suffering from renal insufficiency could be regarded as poisoned patients, and should be treated accordingly. Women passing under four hundred grains a day might show a mild degree of nervousness; under three hundred grains the nervousness became more serious, and the taking of a cold would be liable to result in a bronchitis, a pleurisy, or some other malady equally grave. If the solids were reduced to two hundred grains, the condition became very serious, and if to one hundred grains the patient could be regarded as dangerously near uræmic convulsions. By administering appropriate diuretics the symptoms subsided. The paper contained illustrative cases, but the author's chief object was to call attention to the subject in general.

Dr. A. J. C. Skene, of Brooklyn, said that while it was not in order to discuss the President's Address, he wished to express his high appreciation of the manner in which it and the paper of Dr. Etheridge had treated of certain important subjects, especially renal insufficiency. He was fully convinced of the important part played by renal insufficiency in gynecology and surgery. In spite of the great dexterity and antiseptic precautions manifested at our operations, patients were sometimes known to do badly without apparent cause, and he felt sure that it was sometimes due to our overlooking their general condition, and especially the condition of the renal secretion. He believed also that many affections of the pelvic organs had their genesis in functional derangements of the nutritive system, of the nervous system, and of the excretory functions. He was glad attention had been directed to the necessity for taking into consideration other facts in relation to the urine besides albumin and casts. A diminished quantity of urine and of its solid elements might be of great significance in spite of the absence of albumin and casts. There were two classes of cases quite distinct from each other and yet often confounded in treatment. One was the neurasthenic, who required to be built up, the other was the lithæmic, who was depressed and suffering from excrementitious plethora. Forced feeding in the latter case was a great mistake, and resulted in aggravating the lithæmic state. In such a person forced feeding had an effect on the tissues similar to that observed in Strassburg geese.

Decrease of Urine after Operations.—Dr. Howard A. Kelly discussed the question of renal insufficiency from a somewhat different stand-point, or as it occurred after operations. Being unable to find the record of his analysis of the urinary secretion after operation in one hundred cases made on a former occasion, he gave the results, which were similar, obtained in twenty-one recent cases. The work in detail had been carried out by Dr. Clark. The normal amount of urine secreted each day prior to the operation varied from 847 c.c. to 1,277, the average being about 1,057 c.c. The average amount on the day after the operation was 516 c.c., and it gradually increased from day to day until the tenth, when it had reached the normal. The urine during this time was very much concentrated, and formed a thick layer if allowed to stand, the specific gravity being 1.025, or even 1.040. A knowledge of these facts would relieve the operator of much anxiety on finding the urine diminished in important or doubtful cases.

Dr. W. E. Ford, of Utica, thought the amount of the urinary secretion under the circumstances mentioned in the papers depended largely upon emotional influence.

Dr. Baldy, of Philadelphia, thought the gynecological condition in the cases referred to did not depend upon the neurasthenia, etc., but was rather the cause of the latter.

Dr. Bache Emmet, of New York, impressed the practical lesson of preparing our patients for two or more weeks before the operation by attention to the alimentary tract and the kidneys.

Dr. Lapthorne Smith, of Montreal, had his patients drink freely of water, especially after operations, and believed that it went far to obviate depression and the pains and aches due to the deposit of uric acid in the joints and muscles. Having observed that he himself had suffered nearly as much as his patients after operations, due doubtless to very free perspiration and loss of the fluids of the body, he had taken to drinking freely of water and had thus obtained complete relief.

Dr. Etheridge, in some closing remarks, said that before operations if he found the urine much diminished, he waited until it could be brought up to at least the normal amount. Like Dr. Smith, he had found that wounds in patients whose system was not saturated with uric acid healed more readily.

Indications for Total Castration by the Vagina.—Dr. Charles Jacobs, of Brussels, the author of this paper, occupied a seat on the platform while the paper was being read by Dr. Henrotin. The reader said that on the present occasion he would only give the results of practice; what he had done, how and why he had done so, the good and bad results obtained. As a general rule it might be said that vaginal hysterectomy found its indications in: 1. Uterine cancer; 2, fibroids of the uterus; 3, extra-uterine pregnancy; 4, total genital prolapse; 5, inflammatory diseases of the appendages; 6, chronic and incurable disease of the appendages and uterus; 7, diseases of the uterus after abdominal operation.

Since 1889 he had done the operation 403 times, with 391 operative cures, 12 deaths, the death-rate being 2.9 per cent. In uterine cancer vaginal hysterectomy had very clear indications. To practise the operation with success there must be, integrity of the vaginal cul-de-sac, complete mobility of the uterus, and a general satisfactory state of health. Forty-five of the above list belonged to uterine cancer, 1 death. Of the 44 there had been no return of the disease in 5, four years after the operation. The return in the majority was not until after three years.

Regarding fibroids, according to Dr. Jacobs's observation they seldom disappeared after the menopause, bilateral castration was uncertain in its results, medical palliative treatment always gave bad results, hence they should be removed. The operation was less dangerous when the tumor was small, and it should be done through the vagina before the tumor had become so large as to compel interference by way of the abdomen. Number of his operations, 38; 23 of them simple hysterectomies, with 23 cures; 15 hysterectomies by morcellation, 2 deaths, due to exhaustion and cardiac disease.

In extra-uterine pregnancy observation tended to prove that the appendages were always diseased on both sides, and since their ablation was necessary, Dr. Jacobs thought total castration by the vagina was indicated, and it should be done as soon as possible before the development of complications. He had done vaginal hysterectomy in three such cases, accompanied by intra-abdominal hæmatocele, with three cures.

Total genital prolapse was an infrequent indication for vaginal hysterectomy. The operation might be done in the aged and when the uterus was large, not small. He had operated 19 times, 1 death, from concomitant intestinal paralysis.

In inflammatory diseases of the appendages he had done vaginal hysterectomy 272 times, with 6 deaths. Pyosalpinx was present in 142; abscess of the ovary in 15; hæmatosalpinx in 33; chronic ovaro-salpingitis in 82. There was one danger in hysterectomy, namely, consecutive fistulæ, which could be classed us: 1, Peritoneal; 2, vesical; 3, ureteral; 4, intestinal fistulæ. Out of the 403 hysterectomies he had observed subsequently intestinal fistula in 5, vesical in 3, ureteral in 1. One of these patients died after resection and anastomosis with Murphy's button.

Consecutive hemorrhage was a bugbear which would only stop the timid. Out of 157 cases of serious suppuration he had left a part of the appendages twenty-one times, but he had not been obliged to have recourse to supplementary operations by reason of tardy complications. The mortality in suppurative diseases of the appendages operated upon by laparotomy by such men as Terrier and Pozzi was six and eight per cent. in 96 and 99 cases respectively; by vaginal hysterectomy, Jacobs, 157 cases, 3 deaths, or 1.9 per cent.; Péan, 350 cases, 7 deaths; Richelot, 56 cases, 5 deaths, and so on, up to 816 cases, with 36 deaths, or 4 5 per cent. In suppurative disease, therefore, Péan's operation was, he claimed, incontestably superior to laparotomy. In non-suppuration, the Péan operation gave a mortality of 1.7 per cent. in 584 cases, which was as good as laparotomy. Total castration by the vagina gave better after-results in bilateral disease of the appendages, and was less dangerous. The indications for vaginal hysterectomy were the same as those for bilateral ablation of the appendages by cœliotomy. A sufficiently exact diagnosis could usually be made before operating, but the vaginal opening could be used simply for exploration should this show total castration to be unnecessary. To do cœliotomy and leave the uterus after removing the appendages from both sides, would expose the woman to future uterine disease, pelvic pains, and nervous disorders.

In chronic and incurable diseases, among them pelvic neuralgias and tuberculosis, Péan's operation gave much better results than laparotomy. Out of six cases of this kind operated upon by Dr. Jacobs, five had remained cured of their symptoms.

The discussion on Dr. Jacobs's paper was postponed until after the reading of Dr. Wathen's and Dr. Henrotin's

Vaginal Hysterectomy for Uterine Myomata and Diseases of the Adnexa.—Dr. W. H. Wathen, of Louisville, read a part of his paper on this subject. It contained recent information from Péan, Richelot, and other European operators who followed Péan's method of operating through the vagina. The general mortality from total vaginal castration according to these figures had been 4.16 per cent., but it was to be observed that it was smaller for the more recent series of cases notwithstanding the fact that pelvic suppuration had been a more common indication. It had been claimed that, since hysterectomy should not, with few exceptions, be performed if the ovary and appendage on one side was healthy, we should not approach by way of the vagina unless we had positively diagnosticated bilateral disease. But this objection was not valid, for cœliotomy could be immediately performed after establishing the diagnosis through the vagina, and the opening thus made would serve for more complete drainage. But where the tubes and ovaries were removed from both sides, the uterus could serve no purpose and should also be removed.

The following were some reasons why vaginal hysterectomy should be preferred to cœliotomy: 1. There was more rapid and complete convalescence, the patient usually sitting up within a week and walking about a few days later; 2, in pelvic suppuration there was less danger of infection from soiling the peritoneum; 3, absence of mural abscess; 4, absence of subsequent hernia; 5, restoration to health in a greater proportion of cases. The preliminary preparation for vaginal hysterectomy and cœliotomy was practically the same. The vagina should be made as aseptic as the abdomen.

Conservative Surgical Treatment of Para- and Peri-uterine Septic Diseases.—Dr. Fernand Henrotin, of Chicago, read on this topic: Women came to us to be cured of their symptoms of the vaginal flow, pains, etc.; to them a pathological cure was of minor importance. The professor and hospital surgeon sent them home, after two weeks, cured of an operation, but often not of the disease. It was the author of one laparotomy who always knew the remote as well as the immediate result. Salpingectomy and salpingo-oöphorectomy had often failed to cure the patient with peri- and para-uterine septic disease, and of recent years it had become the practice also to remove the uterus. Having laid hands upon the ovaries, it did not matter what became of the uterus. The time, however, for showing sentiment was before the ovaries had been touched. Women with pyosalpinx, oöphoritis, pelvic abscess, etc., whether of catarrhal, puerperal, or gonorrhœal variety, did sometimes recover completely without radical operation. The gynecologist of the future, if he had a conscience, must learn to carefully discriminate between cases. This whole subject would have to be gone over again by some master who had pathological knowledge combined with experience.

Dr. Henrotin wished to direct attention to the management of the class of cases under discussion in their incipiency. This would usually fall upon the general practitioner, since he alone usually saw the case in the first stage. The time to cure septic inflammatory diseases, completely and perfectly, was within the first week of their appearance. The treatment which Dr. Henrotin recommended and had practised in the limited number of cases which he had seen the past two or three years, was to make an incision behind the uterus and explore the pelvis. The vaginal incision carried with it little if any danger. He had operated on twenty-seven cases, and all had made a satisfactory and apparently permanent recovery. Just as soon as there was evidence that the disease could not be reached from the interior of the uterus, make the incision behind, and one would have a good chance to abort the disease before it had gotten beyond control. What was the present practice? We gave a douche, put on a poultice, quieted pain with morphine, and allowed the case to go on. In contradistinction to such a hopeless policy the author recommended vaginal incision, posterior to the cervix, parallel with the axis of the vagina and downward, introduction of the finger. If nothing but an exudate was found, the patient would get well in a few days, with freely movable pelvic organs. He urged, then, cure of the disease in the beginning by simple incision and drainage.

(To be continued.)

New Treatment for Diabetes.—Lépine (*Sem. Méd.*, April 24, 1895) records the result of the treatment of four cases of diabetes mellitus with a glycolytic ferment prepared from the diastase of malt. In all four cases there was distinct improvement, and details of these cases are given. As regards the sugar excretion, in the first class, before treatment the mean quantity for the twenty-four hours was 140 gm.; under the influence of the ferment it was 70 gm. In the second case the sugar was reduced from 41 to 11 gm.; the third case from 116 to 80 gm.; in the fourth case from 257 to 124 gm.; but later only to 163 gm. The ferment is not diuretic; it has no injurious effects, but the improvement is only temporary.

It Stands Alone.—A Paris medical journal refused to receive yearly subscriptions. The editor who writes the whole monthly edition himself evidently fears that either he or the reader will grow suddenly weary.

The Foundling Asylum in Rome has been closed because of the great mortality among the inmates.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

SUMMER SESSION — ROYAL SOCIETY — SANITARY CONFERENCE AT MANCHESTER — LONDON AND PROVINCIAL DEATH-RATES — OBSTETRICAL SOCIETY — WHITE LEG.

London, May 11, 1895.

We are now in the full work of the summer session at all the medical schools, so that the hospitals have put on a more animated appearance. The short recess seems in many instances to have rejuvenated the workers, although others look as fatigued as ever, perhaps because they took no holiday.

Among the newly elected Fellows of the Royal Society are Drs. MacEwen and Sidney Martin and Mr. W. H. Power. At the annual *soirée* of the Society there was, as usual, an interesting exhibition. The spectra of the newly discovered element, argon, and of a mixture of argon and helion, were shown by Professor Ramsay. Mr. Galton exhibited plates of finger-prints (magnified) illustrating the method of identifying criminals which has recently been practised. Another striking exhibit was that showing the conveyance of contagium by flies. These insects have often been suspected, but I do not remember any proof like that offered by Mr. W. T. Burgess on this occasion. He places flies for a moment in contact with cultivations of bacillus prodigiosus and then lets them escape in a large room. After a time, often several hours, he catches them and makes them walk over sterilized slices of potatoes, which are then incubated, when vigorous growths of the organism appear. This looks as if the danger from flies has not been fully appreciated.

There were many other exhibits, among them that of the Marine Biological Society illustrating the effect of light in the pigmentation of flat fish.

Manchester enjoyed a sanitary conference at the end of last month and also a conference of district councils on registration of plumbers. Sir H. Roscoe introduced the subject of smoke abatement. Mr. Fletcher, chief inspector of alkali works, urged that coal-smoke should be the subject of regulations as much as vapors of chemical works. The Earl of Meath was strong on his favorite subject of open spaces, and especially playgrounds, for children and women. The ventilation and lighting of schools, the value of winter gardens and recreation halls, and other subjects were also freely discussed.

The Registrar-General's returns for the first quarter of the year are now issued, from which it seems that in the 33 large English towns 66,503 deaths were registered during the three months, corresponding to an annual rate of 25.2 per 1,000, against 25.8, 22.0, and 21.0 in the same period of the three preceding years. In London our rate was 26, while it averaged 24.6 in the 32 large provincial towns. The diphtheria rate in London was 0.39; in the provinces, 0.24. Infant mortality was 159 in London, and 162 in the provinces.

The annual meeting of the Obstetrical Society of London was held Wednesday, May 1st, when Dr. C. Hubert Roberts gave details of sixteen cases of so-called white leg, most commonly met with after confinements, and of which he proposed the following classification: 1. Cases due to pressure. 2. Cases associated with general disease. 3. Cases of a true septic nature. 4. Cases of thrombosis apart from sepsis. 5. Cases of thrombosis and sepsis combined.

Dr. Horrocks was not sure that the author had made out a difference between Classes 4 and 5, and asked on what grounds the conclusion was reached that some cases of thrombosis were not due to any form of sepsis. He believed both forms of white leg to be due to some

form of sepsis. It was possible that in some cases clotting in the veins was more marked than in the lymphatics, while in others the lymphatic element predominated, but this fact did not exclude sepsis. He pointed out that sepsis was not negatived by the absence of any evidence of para- (or peri-) metritis, for the micro-organism might not give rise to any inflammation of the connective tissue.

Dr. Herman thought that these were cases of "swelled leg," and not what is technically called or described as "white leg." Thrombosis might exist apart from sepsis, and this was quite a different complaint from thrombosis with sepsis. It would be interesting to know whether white leg occurred in cases in which thorough antiseptic precautions had been carried out, but they had no statistics as to the frequency now and before the introduction of antiseptic methods. In the rare cases in which women suffering from phlegmasia alba dolens died they died in quite a different way to those who obviously succumbed to sepsis. Swelled leg from thrombosis was a different thing from true phlegmasia dolens. Though there was little or no anatomical evidence of the disease being due partly to thrombosis and partly to lymphangitis, there was clinical evidence.

Dr. A. Routh suggested that if the author had seen these cases quite in their original state he might possibly have discovered some of the characteristic appearances of true phlegmasia dolens. One did not usually see these cases until the first stage had passed off, and he related a case to show that it was quite possible that most of the so-called cases of thrombosis might have begun by lymphangitis.

Dr. Macnaughten Jones felt more disposed to adopt Tilbury Fox's view that the affection began in the lymphatics rather than in the veins, and possibly some of the differences observed might be due to the predominance of the changes in the veins and in the lymphatics respectively. He agreed with the view that the affection sometimes occurred independently of sepsis. Pressure as a cause was proved by two cases which he had met with, in which no symptoms whatever of any septic condition were present previously to the supervention of the characteristic appearances of phlegmasia. This pressure had been accounted for anatomically by the peculiar injuries to which the left side of the uterus was supposed to be liable, but that view did not commend itself to him. He pointed out that on the left side the artery overlay the vein, which was a more likely cause of pressure.

Dr. Griffith agreed that there were essential differences between the disease as described in text-books and cases due to simple thrombosis. He did not think the author's explanation was quite admissible as to the cause of the thrombosis. He had examined two cases very carefully post mortem, and in both the thrombosis had extended from the uterine sinuses right up the uterine veins. Given the size of the uterine veins it was quite conceivable that they might be thrombosed without giving rise to any constitutional symptoms, and it was not until there was a sudden interference with the circulation in such a large part as the leg that one got the characteristic symptoms.

Dr. Robinson said Vidal discovered in many of these cases a streptococcic invasion of the thrombosed veins.

The President—Dr. Champneys—said the discussion showed how obscure the pathology of this condition still was. The author has cleared the ground somewhat by pointing out the difficulties that beset any theory of these curious affections which were lumped together under the term "white leg." He failed to see that Class 1 was necessarily different from Class 4, because pressure would be very likely to lead to thrombosis. In speaking of sepsis it was necessary to define exactly what was meant. Did the author mean by sepsis such a condition as sometimes culminated in puerperal fever? That could not be the case in white leg of any sort, otherwise the majority would die, whereas a fatal termination was very rare.

Dr. A. Giles observed that in only one case was the history of sepsis at all definite, and that was the one in which there was abscess with sloughing.

Dr. Roberts, in reply, said it must be remembered that one got thrombosis of the veins of the uterus and broad ligaments without there being any appreciable sign on examination. Personally he did not believe that many of these cases originated in lymphatic disturbances.

THE RECENT EVOLUTION OF SURGERY.

ABRIDGED REPORT OF THE ORATION AT THE MEDICAL SOCIETY OF LONDON, MAY 20TH.

(From our own Correspondent.)

London, May 20, 1895.

The Conversazione of the Medical Society of London was held on Monday last, when the annual oration was delivered by Mr. Pearce Gould, who took for the subject of his discourse the changes that have come over surgery during the last twenty-five years, changes so important that progress seemed to him too tame a word to indicate the development of the spirit of surgery and its increased adaptation to the requirements of mankind. So the orator proposed to call these changes "evolution;" though how that is a more descriptive or more forcible name than progress may puzzle many to see. Mr. Gould pointed out and illustrated with considerable force five changes which are comprised in this evolution. These are: 1. The removal of the formerly admitted anatomical restrictions upon surgical operations, sometimes spoken of as the extension of surgery into new regions, but that is a very imperfect expression of the facts, and conceals their true significance. Trephining probably dates from prehistoric times, but up to a very recent day surgeons have only removed bone, and carefully abstained from interference with the brain. Trephining is now only an incident in an operation directed to treatment of the membranes of the brain. So our immediate predecessors operated timidly, if at all, upon the posterior part of the vertebral column. Of the surgery of the thorax the same holds true. Operations upon its walls were sanctioned long ago, and timid efforts were made occasionally to open and even drain the pleura. Now, not only the pleura but the lung itself is freely operated upon, and the chief bar to further pulmonary surgery is the difficulty of precise diagnosis and localization of lung diseases. The pericardium is aspirated or drained without hesitation, and the suggestion has been made not only to tap the heart itself, but to treat wounds of its muscular substance by careful suture. The mediastinum, too, is now within the pale of legitimate surgery. No single organ in the great cavity of the abdomen is now held to be beyond the reach of the surgeon's knife. The removal of huge abdominal tumors is a commonplace event, and surgical methods extend to all the abdominal viscera.

Until quite recently surgeons recognized that many organs and parts of the body lay beyond the limits of legitimate surgical interference, and admitted it to be no reproach to their art to refuse to interfere with the peritoneum, the kidney, the lung, or the brain. A surgical operation was thought to be in its very nature lethal; certain tissues and organs were held to be of such anatomical delicacy that to submit them to operation was to court disaster.

Surgeons who saw the removal of a subcutaneous fatty tumor entail suppuration and the risk of blood-poisoning could not contemplate with approval the removal of a kidney. When the surgical wound of a healthy joint was seen to be attended with the gravest

risk to limb and even life, how could a surgeon dare to lay open and operate freely upon a huge serous sac like the peritoneum? When every surgical procedure entailed grievous risk, and no means were known of certainly avoiding it, all surgeons felt the necessity of limiting operations to the irreducible minimum, and when it was forced upon them that the deeper their incisions the greater the peril, what else could they think than that the mere depth of an organ, and the means taken by nature to protect it from external violence, were a clear intimation of its being beyond the scope of surgery? To-day we know that simple, well-executed surgical procedures are not in themselves pathogenic, and that every tissue and organ of the body is the seat of a power of repair more than equal to the demand surgery makes. With this knowledge the anatomical barrier to the progress of surgery vanished, and from an anatomical stand-point the only bar to the feasibility of an operation is its mechanical impossibility. But a surgeon is not free to incise anywhere or to excise anything. The very removal of the anatomical restrictions upon the activity of surgeons has brought into relief the physiological restraints upon their art. Thus, while the depth and important relations and the anatomical structure are no bar to the excision of either kidney, the physiological importance of the organs is an absolute bar to double nephrectomy or to the removal of a single kidney when its fellow is *hors de combat* from disease. A wandering spleen has been successfully excised; its place in the organism can be filled by the bone marrow, aided possibly by the lymphatic glands, and sometimes by small masses of spleen tissues left behind in the gastro-splenic omentum. But so far as we know a wandering liver can never be treated in the same way—anatomically the operation is almost equally feasible, but physiologically it is barred. Similarly the medulla oblongata and the central portions of the brain are outside the field of surgery, not because they cannot be reached, nor on account of peculiarity of structure, but because of their physiological importance. The only limit in the anatomical range of his activities that a surgeon now recognizes is the physiological one. He only asks whether he can operate upon it without injury to structures necessary to life, or without inflicting upon the patient greater disabilities than those caused by the disease he has to combat.

2. The higher regard in which the physiological integrity of the organism is now held was the next point. Though no tissue or organ is now held by surgeons to be beyond the scope of their activities, all tissues and organs have assumed a new and higher sacredness in their eyes. Surgery has become more conservative than ever. It is true that diseased structures are removed with greater freedom, and almost regardless of situation. But never before have we seen such efforts made to limit operations to the removal of diseased parts, and to save all healthy structure, as are constantly witnessed now.

3. A new conception of the real nature of a surgical operation, and of the personal responsibility of the operator. An operation used to be regarded as in itself a cause of disease, and suppuration was thought sometimes a physiological and not always a pathological process. Surgeons were called "brilliant" if only they could operate with despatch and dexterity. If a large proportion of recoveries was obtained, the man was apt to be called "lucky;" if failures predominated, again it was his "luck;" shoulders were shrugged, the Deity was blamed, and the surgeon took comfort in his "brilliancy." To-day, this is a dead language to us. Instead of brilliancy in execution, we demand success; instead of speaking of "luck," we talk of surgical responsibility! Operations still fail, but instead of blaming the Deity, we now blame ourselves for it. For how do failures arise? We may attempt what we are unable to effect, but such attempts should be made so as not to add to our patient's ills; we ought, at least, not to introduce any new elements of danger where we cannot effect relief. An operation may be fatal from shock, or by the infliction of some injury to a really vital part, or by what is called an accident, such as uncontrollable hemorrhage; or it may be the means of infecting the patient's healthy tissues with virus introduced from without or from within from the patient's own tissues.

4. Surgery has apprehended that its highest ideal is to treat directly the causes of disease. Up to the last few years surgical methods, as applied to disease, were crude. They consisted of the removal of pathological products, as by amputation, the relief of tension, and the application of physiological rest; knowing nothing of the ultimate causes of disease, nothing could be done to combat them.

Let us fasten attention upon the change of thought itself rather than upon its practical outcome. Take merely, for example, tubercular disease. For tubercular disease of lymphatic glands the old practice was the opening of abscesses, and in this it only slightly anticipated nature. To-day this plan is almost never adopted except as a temporizing expedient or a preliminary to a more radical operation. But the surgeon directs all his efforts to one end—the removal, not only of the effete products of the disease, but of the active cause of the disease itself, the tubercle bacilli. As a result, we have our patients well in a few days instead of their lingering on with slow suppuration for months and years, exposed all the time to a real peril of more widespread tubercular infection.

5. The last indication of surgical evolution brought forward by the orator was physiological operation. By this term he meant any operation on a part which was not the seat of the disease nor yet the cause of the disease, but by influencing which we may beneficially affect a morbid change in another part. Of this kind of substitutionary surgery normal ovariotomy for uterine fibroids and castration for diseased prostate were examples. Mr. Gould did not offer any opinion on the results or value of these operations, but only named them as instances of the outcome of a new idea in surgery which may be the beginning of a new epoch.

OUR PARIS LETTER.

HYPNOTISM—SUGGESTION—ABSINTHISM—DECREASE IN THE FRENCH POPULATION—PROFESSOR LABORDE'S EXPERIMENT, ETC.

PARIS, May 25, 1895.

THE important and, we may add, alarming questions of hypnotism and suggestion have passed far beyond the domain of medicine and are being now vulgarized by the laity as well as employed by charlatans, masseurs, electricians, somnambulists, and mesmerizers of all sorts, sometimes criminally. A curious case has just been brought to light in the courts. A man and his wife, named Jouve, took up their abode in the house of a woman living at Lyon, whose husband had recently died very mysteriously—Jouve, unknown to the deceased or his wife, being in the house at the time, and taking up his abode with the widow, as had been indicated to him, he said, in a dream. They magnetized her repeatedly, put her into hypnotic sleep, provoked attacks of hysteria, and caused her to live in a state of perpetual ecstasy until her death, a few months after that of her husband, when it was found that Jouve had obtained a power of attorney over her entire wealth. The trial is still going on, and the setting aside of the will is demanded on account of suggestion.

A very interesting report on this subject has just been published by Doctor Lacassagne, recalling the legendary quarrel between the schools of Paris and Nancy which

the Parisian jury had to consider at the trial of Gabrielle Bompard, the mistress of Eyraud, who asserted that she was hypnotized by Eyraud and committed the murder by suggestion. These are the two leading schools of the world in this branch of science; the school of Nancy, with Bernheim at its head, asserting that hypnotism is an inferior state, a sort of dividing into two of the soul. The school of Paris replying through the illustrious Charcot that the hypnotic state is a disease of the nervous system, a disease that can be provoked and realized in hysterical subjects only. It is difficult, indeed, to lay down any fixed rules or dogmas in matters so far-reaching as hypnotism and suggestion; and while the school of Paris is undoubtedly right in the main and as regards true hypnotism, yet it loses sight of that more general and lighter form of hypnotism that medical men see on all sides to-day. One may be hypnotized by a picture, or a horse with richly silver-plated harness, and while the state lasts, which in this case may be more or less transitory, any suggestion made will be carried out, or at least an attempt will be made to carry it out, and then the charm is broken, and the subject at once returns to him or herself. The Nancy school assert, on the contrary, that the hypnotic state thus induced is permanent, and cite an instance of hypnotism and suggestion riding in a railway carriage, where the subject was hypnotized simply by being looked at fixedly in the eyes, and made to carry out the suggestion some months later and at several hundred miles' distance from the hypnotizer. It is this kind of hypnotism in comparatively healthy but negative subjects that the Paris school refutes altogether. The writer has known instances of this kind of fascination in which the subject was suggestible momentarily —fascination is the word—a wide difference from true hypnotism, of which it is only the first stage, and such subjects are mostly incapable of being really hypnotized.

To show how wide-spread the hypnotic idea has become we note that the Société d'Hypnologie is now devoted not only to medical hypnotism but tends to embrace the domain of psychology and sociology, the Review of the Society having just published an essay by Dr. Regnault on the social utility of suggestion.

Speaking of fascinations, we are led to mention one that is very largely on the increase not only in Paris but all over France—absinthism. Driving in any part of Paris in the morning about half after eleven o'clock or in the evening at six, one sees hundreds of Frenchmen and women seated at the little tables in front of the cafés drinking, and three out of every four are sipping absinthe. This distillation of an herb that grows in some parts of France and Switzerland contains, besides alcohol at eighty-five per cent. an essential oil which possesses for absintheurs a fascination. The liquor when poured out resembles in color Scotch whiskey, but when a perforated silver spade is put across the top of the glass with a lump of sugar on it and water allowed to drip slowly through, it assumes an opalescent green color with a taste of anise-seed. It is now ready for consumption, which requires from one-half to three-quarters of an hour. The absintheur then goes home with an excellent appetite and lies down at night to voluptuous dreams. Next morning he awakes quite well and the absinthe of the day before acts as a mild aperient. But soon the scene changes, and in a few years or a few months, as the case may be and as the number of glasses a day has been smaller or larger, we see him a prey to tremblings, epilepsy, dementia, neurasthenia or convulsions, cerebral or spinal congestion or paralysis, etc. For this one, two, three, or at most four absinthes a day are enough. One of the first actions on the nerve-centres is to annul all sexual desire, and it is for this cause, absinthe, that the population of France is decreasing, while suicide, crime, insanity, and diseases of the nervous system are increasing.

Professor Laborde injected recently, before his class, 1 c.c. (between fifteen and twenty drops) of the essence of absinthe into a guinea-pig, which died after a series of epileptiform convulsions. During the intervals the animal stiffened itself on its four legs, curved its back in *arc de cercle*, and then fell down repeatedly, agitating its fore paws wildly and crying piteously until death ended its sufferings in forty-five minutes after the injection.

THE NEW YORK STATE MEDICAL LAW.

To the Editor of the Medical Record.

Sir: So many requests for information relating to the medical laws of the State are being received that it has been thought proper to call the attention of the profession to a feature of the existing law which expires by limitation on August 1, 1895. Paragraph 148, chapter 661, of the laws of 1893 provides that persons "who matriculated in a New York medical school before June 5, 1890, and who received the degree M.D. from a registered medical school before August 1, 1895, may without further examination, on payment of $10 to the regents and submitting such evidence as they may require, receive from them an indorsement of their licenses or diplomas conferring all rights and privileges of a regents' license issued after examination." From this it will be seen that after August 1, 1895, whether or not matriculated previous to June 5, 1890, all persons desiring to practise in this State must pass the medical licensing examinations. It will therefore be well for all entitled to the privilege of this exemption to file their applications for indorsement with the regents as soon as possible.

The Legislature of 1895 has restored the penalty feature of the law as it stood previous to revision by the statutory revision committee, and medical malefactors and others unlicensed and unregistered may once more be prosecuted in the criminal courts. A vigorous enforcement of the laws by county medical societies is urged in the hope of the benefit to be derived by the public as well as for the good name of the profession of medicine. The Legislature of 1895 has also passed a law which will make it necessary for every person receiving the degree of M.D. from a medical college in the State of New York, after the year 1900, to have had an academic education equivalent to graduation from a first-class high school or academy.

Respectfully,

Maurice J. Lewi, M.D.

New York, June 11, 1895.

THE ORAL EDUCATION OF THE DEAF.

To the Editor of the Medical Record.

Sir: Since it is to the members of the medical profession that parents first go for advice when they discover that the hearing of their children is impaired or destroyed, it is a matter of importance that they should be well posted concerning the educational possibilities for the deaf. The point that the medical specialist and general practitioner alike care especially about is what results are obtained and where they are obtained.

It has been my observation throughout the years of my connection with the oral education of the deaf, that a surprisingly small number of people have a true understanding of the extent to which such education is carried and the degree of perfection attained. Everyone knows that the deaf are educated and that some of them are taught to speak. The impression, however, seems to exist in the minds of many that this education is always imparted by means of signs. The fact that a large part of the deaf children under instruction in the United States and Canada are taught as wholly without signs, and as entirely by means of speech as their hearing brothers and sisters is not so fully understood.

The term "signs" is used by the public indiscriminately for two very different means of communication, whose only likeness is that they both employ the hands. I refer to the manual alphabet and to gestural signs. Most people mean by the term "signs" applied to the deaf, any systematic use of the hands to convey information. To them finger spelling and the making of gestural signs are much the same thing. They are, however, in reality widely different. The manual alphabet is English spelled on the fingers, letter by letter, instead of with a pencil, while signs proper are a language as totally different from English in form and construction as French is different from English, and instead of assisting in teaching the deaf their native language it rather hinders them in acquiring it. This is now almost universally acknowledged, even by the men who have taught by signs all their lives, and the sign language proper is being crowded out, and, where still used, is being more and more restricted every year.

Formerly the schools where manual methods are employed did not pay any attention to speech, but of late years the Oralists have made such inroads upon them in the public estimation that in self-defence many of them now give a little time to trying to teach speech as an accomplishment, though not as a working means of communication. But one might as well expect to learn to speak Greek fluently by spending half an hour a day in learning how to pronounce a few words, and all the rest of the time using English. The oral method is gaining steadily upon the manual method, because it gives all that the manual gives of education and something more besides. It gives speech and lip-reading.

The first oral school in the United States was established in 1867, and now there are twenty-two. There were present in the schools for the deaf in the United States and Canada, on November 15, 1894, 9,534 pupils. Of these, 2,525, or 26.48 per cent., were taught by the oral method, that is, by speech on the part of both teacher and pupil, the latter reading the speech of the former by the motions of the lips and the expression of the face. In addition to these, there were 2,534 who were given some instruction in speech in the schools where signs and the manual alphabet are used.

There are now schools for the oral education of deaf children from two years of age to the time when they are old enough and advanced enough to enter college. This growth of the oral method has been due to the feeling that the deaf child needed something more than an education in the ordinary school branches. He needs some means of communication with the world at large. The general public do not know the sign language or the manual alphabet, and never will. The child whose sole means of communicating is by these or writing, is shut out from intercourse with his fellows to a much greater degree than his comrade who, in addition to his education, has been given the ability to understand the speech of others and make himself understood in the same way. To convince one's self that the oral method does this, it is only necessary to spend two or three hours in some one of the best oral schools, where the deaf children can be seen in all stages of their progress, from the little ones just lisping their first words to those in the higher classes struggling with the problems in algebra and the political history of our own country. Talk with them, ask them questions, and get them to ask you questions. It is quite probable that you will not understand some of them at first. Their speech is strange to you as that of a Frenchman with a strong accent would be. But you will soon become accustomed to it as you would to the Frenchman's. The same is true of their reading your speech. No two people speak alike, any more than two people write alike, and a lip-reader needs to become accustomed to your peculiarities of speech just as he would to your handwriting. Another difficulty that strangers often have in speaking with a person whom they know to be deaf is that they think it is necessary to exaggerate their speech. This is a mistake, and adds to the difficulty of the lip-reader. To a really good lip-reader perfectly natural speech is easiest to read. The only thing which does help them in understanding a stranger is a little slowing up on the part of the speaker, that is, making a slight pause between the words, but not between the syllables of a word.

In the education of the deaf there are three great things to be accomplished: The teaching of language; the teaching of speech; the teaching of lip-reading; I have put them in the order of their importance and their difficulty, a fact the truth of which very few people outside the ranks of the teachers of the deaf realize. I venture to say that nine out of ten of the readers of this paper if asked which of these three presented the least difficulty to the teacher would reply, "the language." As a matter of fact, in practice it is the greatest task of the three. No one who has not been a teacher of the deaf realizes how hard a thing it is to give a congenitally deaf child a thorough mastery over the English language. It is upon this point that the burden of instruction is brought to bear, whether the method be manual or oral, and the understanding and use of language serves as an excellent criterion of the success or failure of a system of instruction.

After the founding of oral schools in this country, where children are not received under six years of age, the next most important departure was the opening of one or two schools, or rather homes, where children are received at a very early age, even as young as two years. Few people realize the importance of beginning the speech-training of deaf children at the same time that a hearing child begins to try to talk. It is now being very generally recognized that the deaf child should be treated as nearly as possible as a hearing child, and we have found that it is possible to treat them much more nearly as the hearing are treated than anyone supposed ten years ago.

It is a fact that the voice of a young deaf child is perfectly natural in his laugh and cry and other voluntary noises. It is beginning to dawn on the minds of a few people that it may be the methods of instruction that make "deaf-mutes" of deaf children and not the fact that they cannot hear. In other words, that if we adopted a somewhat different method of procedure we should turn out our pupils with natural, agreeable voices, and a readiness in understanding speech that is now unknown. Some are coming to believe that it is because the methods employed with the child who can hear are so widely departed from in the case of the child who cannot hear that better results are not obtained. The opening of these homes for the training in speech of very young children is a long step in the direction of realizing the conditions desired by these "advanced thinkers." I have heard parents say, "How dreadful to send a little baby only two years old away to school!" They do not understand that what they call schools are nothing but ideal homes for deaf children, where they receive all the care and petting that they would receive at home, and yet in a way that is continually bearing upon their after happiness. If the mother and father and brothers and sisters could only have studied the situation and needs of the deaf child they could do just as much for him at home during these early years. But they do not, and the result is that these precious years are thrown away.

Through all the past years the oral education of the deaf has been going on supported by the State and occasionally by private beneficence. And even in those oral schools which approximated most closely to schools for the hearing, the deaf were regarded as a class by themselves, to be surrounded by different conditions from their hearing brothers and sisters of the same social grade. When it chanced that there was a deaf child in a family of wealth and refinement, the

parents visited the public schools, and after seeing the conditions made necessary even in the best schools by large numbers and state support, they went home, and after considerable difficulty obtained a teacher to instruct their child at home, excluded from companionship with children of his own age, and shut out from the stimulus and incentive of association with others in the same work. There was no other alternative. They looked for a school for their deaf child offering the same advantages, socially and educationally, as those open everywhere to their hearing children, but such a school was not to be found. So, though they realized that it would be far better for their children to go to school than to stay at home, they were obliged to content themselves with that solution of the problem.

After the opening of the schools for very young deaf children, perhaps the next most marked step forward in the work of placing the deaf child on the same level with his social equals, was the establishment in New York City of a school, organized on the same scale of equipment as the finest and most expensive schools in the city for those who can hear. Here the surroundings are those of a wealthy and refined home, and at the same time the pupils are carried from the beginning of their instruction to, and even through, the regular course for a degree in the colleges of the city. This has never been possible for the deaf before, and thus the last section is completed of the long road by which the deaf child is led from a path that seems hopelessly divergent from the road travelled by the child who can hear, back to union with that road when it reaches college. Few people are aware that the education of the deaf is carried so far, and many will be surprised to learn that a boy will enter Columbia College in the City of New York next October, whose entire education has been obtained since he was deaf, and wholly by the oral method, and that another is expected to enter a year from that time. These boys are subject to the same standards and requirements as their hearing fellows.

Just one example to show what can be accomplished in speech and lip-reading. Last summer at the convention of the Oral Teachers of the Deaf, at Chautauqua, a gentleman who is on the staff of the *Review of Reviews*, saw a little girl whom he knew to be deaf writing a letter at one of the tables in the hotel lobby. On the other side of the table sat a young lady whom he supposed to be the child's teacher, and as no newspaper man misses an opportunity to obtain information and talk to a pretty girl at the same time, this gentleman stepped up, and politely doffing his hat, said, "Pardon me, but may I ask you to tell me something about the methods employed in teaching a young deaf child like this little girl?"

"I am afraid I cannot give you a very good idea," she replied, "but I will try." Whereupon she went on to tell him a little about the methods employed. When she had finished he thanked her and said, "May I ask in what school you are a teacher?" "Oh! I am not a teacher, but I am a graduate of a school for the deaf," was the answer. The gentleman was completely taken aback, and after expressing his surprise and complimenting the young lady upon her wonderful success, he came over to me and said: "There's a young miss over there who thinks I come from the back districts, and just tried to make me think she had been deaf since she was a baby." "Well, I know it to be true," said I.

Results as perfect as this cannot, or at least have not, been produced in every case. But a degree of success is obtained that more than warrants the expenditure of the time and money in the process. I have often been asked what proportion of the deaf can be advantageously taught by the oral method. My reply is, one hundred per cent. of those that can be taught by any system. The cases of malformation rendering speech impossible are, as every physician knows, very rare, and if begun at an early age both speech and lip-reading are possible to every child of normal mind.

Nor are the benefits of lip-reading confined to those who have been deaf from infancy and those who are totally deaf. Adults who have become deaf or even hard of hearing, can be taught to understand the conversation of others by the motions of the lips and the expression of the face, without requiring the speaker to raise his voice. By this means it is quite possible for adults who are totally deaf to mingle freely in society without anyone suspecting that they cannot hear.

JOHN DUTTON WRIGHT.

42 WEST SEVENTY-SIXTH STREET,
NEW YORK CITY.

ANTITOXIN IN SCARLATINA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I notice in the MEDICAL RECORD of May 25th, in the report of the meeting of the American Medical Association, in the Section of Diseases of Children, that in reporting my case of antitoxin in scarlatina credit is given to Dr. Clark Parker.

The diagnosis of scarlatina was made on Saturday morning. Sunday the appearance of the case would ordinarily have been diagnosed as true diphtheria. Although the cultures made from Sunday's and Monday's specimens did not develop the Klebs-Loeffler bacilli, and although chains of streptococci were discovered, the case was unquestionably either one of mixed infection or of malignant scarlatina. Antitoxin was used, one injection Sunday, and two injections Monday, 20 c.c. each—a case which would beyond a doubt have been absolutely fatal under ordinary circumstances came promptly under control by the treatment of antitoxin.

W. THORNTON PARKER, M.D.

GROVELAND, MASS.

ON THE PHYSIOLOGICAL ACTION OF PERIODIC INDUCED CURRENTS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I regret that Dr. Goelet in his comments on my communication missed both its spirit and contention. It was in no way a criticism upon his claims, neither was it meant to convey the idea that he "was taking something that belonged to me." Now, however, when he says that a "certain manufacturer asked his permission to wind upon one spool all the different lengths and sizes of wire as he has suggested, and that he granted him permission upon condition that he would only continue its manufacture if I (Goelet) found the results derived therefrom as satisfactory," etc., one's credulity is not a little taxed. On what ground it became necessary to ask any man's permission to use any length or size of wire, is by no means clear. No such permission was necessary, and as I understand it, no such permission was applied for. I do not mean to say that Dr. Goelet did not think that his permission was asked, but simply that he was mistaken.

As a matter of fact, the manufacturer to whom he alludes constructed for my use and at my suggestion, some years before the appearance of Dr. Goelet's article, a continuous coil of nearly two thousand yards, made up of all the various sizes of wire mentioned, and in the MEDICAL RECORD of February 14, 1891, nearly a year before Dr. Goelet's article, may be found my paper on the "Different Physiological and Therapeutical Properties of the Induced Current of Electricity," based upon long experience and experiment with these very coils of low and high tension. Dr. Goelet says that "if Dr. Rockwell described in the *New York Medical Journal* of May 13, 1893, and August 18, 1894, the only improvement that has been made in these coils, it seems evident that he must have taken his

suggestion from my article referred to above, which was published in November, 1891." In view of my previous articles and work along this line, this statement is not altogether agreeable, especially as the improvement to which I referred in this particular instance is quite different from what Dr. Goelet had in mind, and with which he could have had absolutely nothing to do. I will not take time or space to describe it. To anyone reading with ordinary care the article designated in my letter of May 4th, it is readily apparent.

A. D. ROCKWELL, M.D.

May 28, 1895.

New Instruments.

A NEW AND COMPLETE PORTABLE STERILIZER.[1]

By CARLOS C. BOOTH, M.D.,

YOUNGSTOWN, O.

GENTLEMEN: I have the pleasure of showing you a new and compact portable sterilizer for surgical use. This box (Fig. 1), shows a sterilizer ready to put into your operating satchel; or, if you choose, you can have a canvas bag to carry it in, but I prefer filling it with instruments, etc., and setting it into my operating satchel. This box is 12½ inches long, 5¾ inches high, and 5½ inches wide. I remove the cover and from it take a boiling pan which is 2½ inches in depth and 12 inches long, which contains four legs, an alcohol lamp, and a perforated tray for instruments. I now insert the legs into the bottom of the boiler, place the alcohol lamp beneath, and place this box, which has a perforated bottom and is, you notice, flanged in such a way that the condensed steam returns to the boiler, on top of the boiling-pan. This shows the apparatus complete (Fig. 2). This arrangement gives you a complete apparatus for boiling instruments and at the same time sterilizing your dressings, towels, ligatures, sutures, etc. When ready to put the instruments into your operating trays, you lift off the steamer and by means of these handles remove the tray from the boiling soda solution containing the instruments to the stand where your trays are. By putting back the steamer you can keep the contents hot until you are ready to use them. The towels and dressings are perfectly dry as soon as cold after being removed from the sterilizer. There is plenty of room for one half-dozen towels and all the dressing that is needed for any operation. You notice that after I repack this apparatus there still remains plenty of room inside for instruments etc. Thus, the sterilizer takes up a very little room in the satchel. I do not use the lid for a tray, because it is necessary to keep your dressings and towels hot until you need them. The advantages I claim for my apparatus over any other portable sterilizer are, 1, its compactness and amount of room inside for use when in transit; 2, the fact that you can have a separate place where you can keep towels and dressings perfectly sterilized and hot until ready to use them; 3, its cheapness, costing only about half as much as some others on the market. It is constructed mainly of German silver and can be had from The Averbeck Company, Youngstown, O.

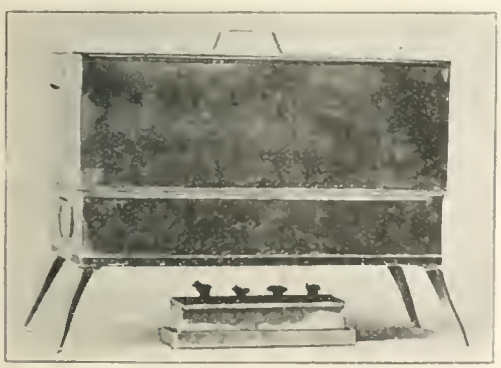

FIG. 2.

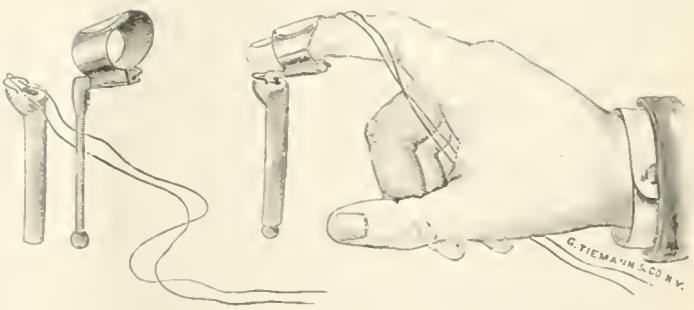
[1] Shown before the January meeting of the Mahoning County Medical Society, Youngstown, O.

A NEW INTRODUCOR AND EXTRACTOR FOR INTUBATING THE LARYNX.

By DAVID C. LEWINTHAL, M.D.,

NEW YORK.

THIS introducor and extractor for intubating the larynx has been devised by me with a view to simplify the ingenious, but somewhat complicated and cumbersome apparatus at the present time in use. The introducor consists of a metallic ring, fitting closely the end of the index finger. Underneath the ring the obturator, which is made of flexible steel, is attached by means of a spring catch. The head of the tube is supplied with a wire rim as shown in the appended cut. The string drawn through the wire rim and passing to the right of the index finger, and being held by the third and fourth fingers against the palm of the hand, keeps the tube attached to the obturator. By releasing the string after accomplished incubation, the obturator need only be lifted out of the tube and the operation is completed. The removal of the tube is accomplished by the extractor, well shown in the cut, and which consists of a metallic ring with a small hook attachment. Lifting the epiglottis, the wire rim can be easily felt by the tip of the finger, which has been left free for the purpose of sensation. A slight pass of the finger, and the hook is caught into the wire rim, and the tube is removed.



The advantages claimed for this introducor and extractor are their simplicity, and hence smaller cost and lesser liability of getting out of order. The tube being attached to the end of the index finger is directly under the sensation of touch, and hence can be manipulated with greater delicacy and the direction of its course can be better determined according to necessity.

The obturator has been made flexible for the purpose of avoiding its catching and extracting the tube after it is once well in the larynx as has frequently happened to beginners. After the tube is in the larynx, the simple release of the string disattaches the obturator from the

tube and thus a few seconds of valuable time are saved, that otherwise would be spent in pushing the tube off the obturator.

The extractor is, above all, harmless. After a few failures no harm has been done, which is more than can be said of the old instrument, where failure must needs be accompanied by trauma to the parts. The wire rim will in no way interfere with the function of the tube, nor in swallowing, as has been demonstrated in one case in which the instrument has been in use. Both the introduction and extraction were accomplished without any difficulty, although at the time the mechanical details were not yet completed. The child got well and apparently recovered its voice sooner than I have been accustomed to see it heretofore.

Thanks are due to Mr. L. Pfarre and Mr. F. A. Stohlman, of the firm of Tieman and Company, for the splendid mechanical details and fine execution of this apparatus.

N. B.—Since giving this out for publication several important modifications and improvements have been made. Among others, one causing the obturator to spring automatically out of the tube after releasing the string. They will be fully described in the near future, and a list of cases in which it is hoped the apparatus will have been used will be appended.

154 Henry Street.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending June 8, 1895.

	Cases.	Deaths.
Tuberculosis	104	115
Typhoid fever	10	5
Scarlet fever	70	17
Cerebro-spinal meningitis	6	9
Measles	333	49
Diphtheria	207	42

The Metric System in Army Medical Practice.—On and after January 1st, of the present year, it was expected that all prescriptions written by Army medical officers in the course of their official duties would have quantity expressed metrically. Notice of this requirement was given in a circular from the Surgeon-General's office in April of last year, so that every one concerned might familiarize himself with the equivalents of ounces and fluid ounces, drachms, scruples and grains in grammes, cubic centimetres and their decimal fractions. It appears, however, that some medical officers found it difficult to get out of the old rut and continued the use of the hieroglyphics and Roman numerals. This was discovered by Surgeon-General Sternberg in his recent inspection of the medical departments of certain military posts. A new circular has therefore been issued, calling attention to this, and stating in positive terms that failure to make use of the metric system will be regarded as a wilful disobedience of orders. Inspecting officers are requested to report officially, through regular military channels, any failure to comply with the instructions promulgated relating to the use of the metric system.—*Journal of the American Medical Association.*

The Treatment of Complete Rupture of the Uterus.—Dr. Cholmogoroff reports the following case: The patient was a multipara who had borne four children by difficult labor, the last of which was terminated by craniotomy, with laceration of the anterior wall of the neck of the uterus (*The American Journal of the Medical Sciences*). The patient recovered completely in three weeks. Examination of her pelvis showed a justo-minor pelvis of moderate contraction. The fifth pregnancy went on normally. When labor commenced, hemorrhage of moderate degree ensued. The patient was under the care of a midwife, who ruptured the membranes. The labor, however, failed to proceed, and the patient was brought into the hospital. On admission, examination showed the fœtus with its long axis parallel with that of the uterus. The head could be felt above the usual position. No heart-sounds were present. On vaginal examination the mouth of the uterus was found fully dilated. In front and to the right could be felt a considerable portion of the placenta. The breech of the child was at the pelvic inlet, the sacrum directed posteriorly and to the left. The right foot was found on the same level with the breech. Hemorrhage, although not excessive, persisted. Accordingly, the right foot of the fœtus was grasped; following this, the hemorrhage did not abate, and accordingly extraction was immediately carried out. As the breech was an inefficient tampon, the hemorrhage continued. The extraction of the child was a most difficult one, and recourse was finally had to craniotomy upon the after-coming head, the opening of the skull being made through the palate. After the extraction of the child, hemorrhage did not entirely cease, and an examination showed the transverse rupture of the uterus at the cervix. The placenta lay in the abdominal cavity among the intestine. The fœtus also had been in the abdominal cavity. After the removal of the fœtus and placenta the hemorrhage did not cease. The condition called for a choice between two methods of treatment, one by cœliotomy, the other by the use of the tampon. As the fœtus had been in the abdominal cavity for some little time, and the entire labor had not been conducted antiseptically, infection of the peritoneum was probable. This would indicate treatment by the tampon. On the other hand, the persistent hemorrhage called for suture of the ruptured uterus. With the idea of accomplishing all that could be done by both, the rent in the uterus was stitched per vaginam through the greater portion of its extent. A long glass tube was passed through the rent into the abdominal cavity, and the vicinity of the rent irrigated with two per cent. solution of boracic acid. A Sims speculum was introduced, the borders of the rent seized with tenaculum forceps, and the greater part of the rent closed by suture. At the left angle of the rent an opening sufficient to admit two fingers was allowed to remain. The bleeding immediately stopped. Through this opening iodoform gauze was passed into the abdominal cavity, and the end allowed to remain in the vagina. The uterine cavity and that of the cervix were tamponed with iodoform gauze; this was allowed to remain for four days, when it was removed and the vagina tamponed with fresh gauze. In eight days the tampon was removed from the abdominal cavity. The patient suffered from mastitis, but otherwise made a good recovery. Cholmogoroff draws attention to this combined method of treating complete rupture of the uterus.

Resection of the Gasserian Ganglion.—Professor Krause has performed this operation several times for trigeminal neuralgia. The effect was in all cases very satisfactory. By this operation it was proved that the trigeminal is the gustatory nerve for the apex and the sides of the tongue.

Professor Marchiafava, of Rome, has been made a Commendatore of the Crown of Italy by King Umberto I.

A CLINICAL AND BACTERIOLOGICAL STUDY OF THE GONOCOCCUS (NEISSER) AS FOUND IN THE MALE URETHRA AND IN THE VULVO-VAGINAL TRACT OF CHILDREN.

A PAPER BASED ON EXPERIMENTS CONDUCTED IN THE BACTERIAL LABORATORY, COLLEGE OF PHYSICIANS AND SURGEONS, COLUMBIA COLLEGE, NEW YORK.*

BY HENRY HEIMAN, M.D.,

ATTENDING PHYSICIAN TO THE CHILDREN'S DEPARTMENT OF THE MOUNT SINAI HOSPITAL DISPENSARY.

BELIEVING that there is still a doubt in the minds of some medical men regarding the identity of the gonococcus in the male urethra with that of the vulvo-vaginal tract of children, and to clear myself of scepticism, at the same time studying the relative importance of the various theories of others, I planned and executed the following experiments. These studies were made upon material from (*a*), the normal and pathological male urethra; (*b*), the normal and pathological vulvo-vaginal tract of children.

In these experiments I used the various media hitherto employed by others, and also employed a culture medium never published, viz., chest-serum agar, a medium upon which the gonococcus can be readily cultivated and to which it can be transplanted. The method of obtaining this I shall describe below. However, I must state, in fairness to Dr. Kiefer,[1] that he availed himself of hydrothorax and ascites serum simultaneously with my experiments. He also employed the medium recommended by Finger, namely, urine-agar, but without obtaining the results which Finger claimed that he obtained. My experiments further included inoculations of a diplococcus found in the normal urethra and the gonococcus in man and in the lower animals. The clinical material which formed the nucleus of my experiments was obtained in part from the pediatric clinic of Dr. Sarah Welt, at the Mount Sinai Hospital Dispensary, and latterly from the genito-urinary clinic of Dr. Hayden and the pediatric clinic of Dr. Huber, both of the College of Physicians and Surgeons, and from the clinics of Drs. Goldenberg and Dessau, to all of whom I take this opportunity of expressing my deep sense of obligation.

Without wishing to burden you with a history of the gonococcus, it is sufficient to state that we are indebted to Neisser[2] for its discovery in 1879. Since then Bokai,[3] Bockhart,[4] Leistikow,[5] and others have endeavored to obtain a suitable medium for its isolation. To Bumm,[6] however, must be given the credit of first having isolated the gonococcus, the results of his experiments having been published in his elaborate monograph. In 1892 Wertheim[7] described a method of making plate cultures and isolating the gonococcus, which gave very good results. Finger,[8] in June, 1894, believed that he had found urine-agar a good medium for the cultivation of the gonococcus. Turro,[9] in July, 1894, published a preliminary paper on the cultivation of the gonococcus, namely, in an acid medium, acid-gelatin and gelatin-gelose (*i.e.*, gelatin agar).

Examinations of Material from the Normal Urethra.—My experiments were conducted in the following manner: The glans was first thoroughly cleansed with soap and water, the meatus held open while a sterilized platinum hook was carefully introduced into the urethra. In the secretions thus obtained I found on cover-glass preparations short and long bacilli, cocci, and small and large diplococci, some of which corresponded morphologically with the ten kinds of bacteria claimed to have been found in the secretions of the normal urethra by Lustgarten[10] and Mannaberg. I then sowed this material, not only on gelatin and agar plates, but also on chest-serum and blood-serum agar, media which were not employed by Lustgarten and Mannaberg. I will state at the outset that I have not been able to demonstrate the gonococcus in the normal urethra. Of the micro-organisms found in the healthy urethra the large diplococcus predominated, while none of the cocci and diplococci became decolorized by Gram's method. Of the various forms of bacteria found in the normal urethra, I have paid special attention to a large diplococcus.

(Fig. 1.) Name, diplococcus urethra; occurrence, in male urethra. Grouping, diplococci; size, larger than the gonococcus; color, negative; temperature, room and body. Relation to air, aerobic. Gelatin plates, shape more or less circular. Colony: Size, from 1 to 3 mm.; edge sharply defined, regular; texture, granular; color, steel blue refraction, circular spot of refraction. Gelatin tubes, surface culture, slight growth, whitish liquefying; puncture, slight growth and liquefying. (Fig. 2.) Agar plates: shape, circular; size, 2 to 4 mm.; edge sharply defined, irregular; texture, granular; color, yellowish. Agar tubes, abundant surface growth, puncture slight growth, grayish-white appearance. Glycerin agar tubes, surface growth abundant, whitish appearance. Urea agar, puncture slight growth, chest-serum, floccular growth. Potato, grayish white growth. Gelatin-gelose, surface cultures, abundant growth, whitish. The same in puncture. Milk coagulated (reaction acid), forming clot, with small amount of serum. Fermentation broth, faintly turbid, white deposit, no gas formation. Uschinsky's medium, slight floccular growth, clear. Acid-gelatin tube, surface growth, whitish growth, the same in puncture, did not liquefy in gelatin. Wuertz's agar, whitish growth, turned red, acid. Pathogenesis, non-pathogenic.

Examinations of the Material from the Pathological Urethra.—The fact that Turro's acid medium was simple and easily available caused me to utilize it as my first experimental medium for the cultivation of the gonococcus. I have strictly followed his descriptions. Turro tells us that gonorrhœal urine is alkaline, and upon standing becomes acid. In 16 cases examined by me it was found that gonorrhœal urine, immediately after passing, gave in 15 cases an acid and in 1 a neutral reaction; 3 cases were neither treated locally nor internally, the others were treated with salicylic acid. Turro further states that by placing gonorrhœal urine in an incubator for twenty-four hours he obtained a pure culture of the gonococcus, and the addition of one per cent. pepton increased its growth. I repeated this experiment and obtained a diplococcus which did not

* Read before the New York Academy of Medicine, May 16, 1895.

decolorize by Gram's method, and therefore believe it not to be the gonococcus. It is also claimed by Turro that he obtained almost a pure culture of the gonococcus in sowing gonorrhœal pus in sterilized normal urine. In repeating this experiment I obtained also a negative result. I claim that Turro's descriptions were deficient in that he did not state the degree of acidity of his culture medium. In my experiments the degree of acidity of Turro's culture medium, gelatin-gelose, was accurately determined and reacted 0.52 acid to phenolphthaleine. The following gonorrhœal cases were examined :

Case I.—Pus from male urethra ; aged thirty-five ; duration eight days ; no internal or local treatment. First infection, cover-glass preparations show gonococci decolorized by Gram's stain. Three gelatin-gelose plates were made ; each one presented cocci not decolorized by Gram's method. Involution form observed; the colony and culture appearance corresponded to the description given by Turro.

Case II.—Pus from vulvo-vagina ; aged two and a half years ; three weeks' standing ; acquired in hospital ; cover-glass preparations show gonococci. Two plates were made. Plate I. showed bacilli ; Plate II., cocci not decolorized by Gram's method.

Case III.—Pus from male urethra ; cover-glass preparation showing gonococci. Culture experiments with Turro's medium negative.

Case IV.—Pus from male urethra ; cover-glass preparation showing gonococci decolorized by Gram's method. Plate I. shows gonococci not decolorized by Gram's method.

Case V.—Pus from male urethra ; cover-glass showing gonococci. Two plates. Cultures simulating in appearance Turro's description, which, however, did not decolorize by Gram's method. Plate I. shows cocci not decolorized by Gram's method. Culture appearance the same.

Case VI.—Pus from male urethra ; cover-glass shows gonococci ; of the two plates made both showed cocci not decolorized by Gram's method.

Case VII.—Pus from male urethra ; aged twenty-six ; two weeks' standing. Has had gonorrhœa three weeks ; was treated locally and internally. Cover-glass negative. Plate I. shows a coccus not decolorized by Gram's method, and culture does not correspond with Turro's description.

Case VIII.—Pus from male urethra ; four weeks' standing ; was treated internally ; no local treatment ; had gonorrhœa previously. Plates I. and II. show cocci not decolorized by Gram's method. Culture appearance corresponding to Turro.

Turro * has successfully inoculated dogs with diplococci, producing a catarrhal urethritis. His result then might be fairly claimed to be the first time that a catarrhal inflammation in the urethra of dogs was produced by inoculation of a micro-organism obtained from the human urethra. Turro attributes his success to an increased virulence of the bacterium by the acid medium. Up to date the only article that has appeared by Turro on this special subject fails to mention the fact that the majority of dogs suffer from either posthitis or balanitis. It is worthy of note that the temperature of dogs fluctuates, the average temperature being 39° C. With your permission I will narrate my own inoculation experiments on dogs with Turro's diplococcus urethræ.

Dog I.—Mongrel race ; male ; had a slight urethral discharge ; cover-glass shows pus ; epithelial cells and numerous bacteria ; cultures taken from urethra on acid-gelatin show cocci not decolorized by Gram's method. Inoculated the diplococcus (Turro) from gelatin-gelose (second generation). After twenty-four hours dog eats little ; discharge somewhat increased. Temperature, 38.7° C. Cultures of material taken from urethra on acid-gelatin and gelatin-gelose and N. agar show cocci not decolorized by Gram's method. N. agar plates show cocci and bacilli, the former not decolorized by Gram's method. Forty-eight hours after inoculation dog eats better ; discharge less ; cover-glass shows pus-cells and bacteria. Seventy-two hours after inoculation dog appears well ; discharge is very scanty ; tongue moist ; appetite is good.

Dog II.—Mongrel race ; male ; has the usual urethral discharge ; cover-glass shows pus-cells, numerous bacteria, and cocci not decolorized by Gram's method. Temperature before inoculation, 39.1° C. The material from the urethra was examined before inoculation on acid-gelatin, agar, and gelatin-gelose ; cocci and numerous other bacteria were found. Twenty-four hours after inoculation with Turro's diplococcus temperature of dog was 39.1° C.; appears to eat well ; tongue moist ; discharge less. Cover-glass shows numerous bacteria and few pus-cells. Forty-eight hours after inoculation, temperature 38.5° C.; other symptoms about the same. Cover-glass shows numerous bacteria. Seventy-two hours after inoculation the dog appears the same as before inoculation.

Believing that my experiments were deficient on account of the degree of acidity of my medium, I thought it advisable to repeat them. My second medium of gelatin-gelose and acid-gelatin responded respectively 0.40 and 0.42 acid to phenolphthaleine. I then examined ten other cases of gonorrhœa of various duration. Cover-glass preparations before sowing pus on medium showed gonococci decolorized by Gram's method. I again obtained characteristic cultures as described by Turro ; a diplococcus about the size of the gonococcus which did not decolorize by Gram's method. This important differential test of the gonococcus (Neisser) from other diplococci in the urethra was not mentioned in his paper. Inoculation experiments on dogs with acid-gelatin culture, 0.42.

Dog III.—Mongrel race ; male ; rectal temperature, 39.1° C. ; presents slight discharge from urethra. Cover-glass from material from urethra shows pus-cells and numerous bacteria before inoculation. I inoculated this dog with Turro's diplococcus. Forty-eight hours after inoculation cover-glass shows pus-cells, small cocci, and numerous bacteria. Cultures taken from urethra on acid-gelatin show bacilli ; those on chest-serum agar show cocci not decolorized by Gram's method. Sixty hours after inoculation dog's condition about the same.

Dog IV.—Temperature, 38.6° C. ; presents discharge. Urethra examined ; cover-glass shows the same as Dog I. Cultures, before inoculation on gelatin-gelose, acid-gelatin, and chest-serum agar, show short bacilli and cocci, the latter not decolorized by Gram's method. Inoculation with the diplococcus urethræ (Turro's) gave the same negative results.

Dog V.—Pug. Temperature, 39.4° C. ; slight discharge. Cover-glass preparation shows the same result as in the other dogs. Cultures before and after inoculation gave also the same result. On account of the severe secondary symptoms following the inoculations as described by Turro, I examined the last two dogs two weeks later and then found them in the same condition as they were before inoculation. I noticed in a paper published by Dr. Wright,[12] of Boston, a foot-note stating that his experiments after Turro's were negative. In reading Turro's article one is impressed with the earnestness of his convictions and conclusions. Nevertheless they are open to the objection that he made no inoculations with his diplococcus in the human being.

The following is the bacterial analysis table of the diplococcus found in the acid media from specific urethritis and corresponds partially to Turro's description (Fig. 3) :

Name. Diplococcus culture, four days' growth.

Occurrence. Male urethra.

Size of Diplococcus. Corresponding to gonococcus.

* Lundström : His inoculations on dogs with a diplococcus from the male urethra resulted in an ulcerative urethritis.

Grouping. Diplococci.
Relation to gelatin. Does not liquefy.
Color. None.
Temperature. Room and body.
Relation to air. Aerobic.

Gelatin plate. Shape circular, size 2 to 5 mm., edge sharply defined and irregular, texture coarsely granular, color yellowish ; most colonies, have circular spots of higher refraction.

Gelatin tubes. Surface growth grayish-white appearance ; does not liquefy. Gelatin puncture, deep growth, did not liquefy on tenth day.

Glycerin-agar tubes. Surface growth gray, white appearance, abundant growth, more than on agar and gelatin.

Broth. Heavy deposit, somewhat turbid.

Fermentation Broth. Both arms turbid, faint pellicle, no gas.

Agar Tubes. Surface growth at room temperature, grayish color.

Potato. Gray-whitish, abundant growth. Milk, whitish deposit, consisting of diplococci ; reaction acid.

Urea Agar. Surface growth slight, growth appears gray.

Puncture. Grayish, slight growth.

Uschinsky's culture. Floccular, whitish appearance.

Gelatin plates. Culture appearance as tops of ivory balls (Turro), after a few days appearing like narrow band or tape.

Acid-gelatin Tubes. Surface growth grayish-white appearance.

Puncture. Deep growth, grayish-white appearance.

Gelatin-gelose plates, corresponding to appearance as on gelatin plates, except more abundant in growth at body temperature, and less transparent. Colony, shape irregular, size 3 to 5 mm., edge sharply defined, irregular, texture coarsely granular, color yellowish, colonies have circular spots of higher refraction.

Gelatin-gelose Tubes. Surface culture grayish-white appearance. Puncture, whitish, growth turned red.

Chest Serum. Abundant floccular growth, turbid. Wuertz's agar, surface culture grayish-white, growth turned red, acid.

My results of the experiments described by Turro having proved unsatisfactory, and being anxious to investigate the subject more thoroughly, I took up the work of Finger, Ghon, and Schlagenhaufer. These writers claim that the best medium for the cultivation of the gonococcus is urine-agar, which consists of one part either sterile or sterilized urine, plus two parts neutral or slightly alkaline broth, containing two per cent. agar and one per cent. pepton, but no salt. According to Finger sterile urine with agar furnishes the best medium for the gonococcus ; nevertheless he does not state how he obtained sterile urine. This would be very interesting. Much of my time was devoted to this point. My first experiment consisted in sterilizing a flask, then cleansing the urethra and glans, especially the meatus, and instructing the patient to urinate directly into the sterilized flask. Placing the urine of five of these cases in flasks in the incubator for twenty-four hours numerous bacteria were found to have been developed. The precaution was taken that the first half of the urine should wash out the bacteria of the urethra. Even this gave a negative result. With properly prepared agar test-tubes, in order to avoid contamination, I then instructed the male subjects to pass the second half of the bladder contents directly into these test-tubes. Petri's plates containing this medium developed at body temperature after twenty-four hours bacteria, and after forty-eight hours deep colonies developed in test-tubes containing N. agar plus urine. My first results with urine-agar for sowing gonorrhœal pus from urethra are as follows :

Case I.—Agar plus sterile urine?* as medium. Urine, 0.53 acid to phenolphthaleine ; specific gravity, 1.023. Male, aged twenty. Gonorrhœa, five days' duration. First attack ; no local or internal treatment. Cover-glass shows gonococcus decolorized by Gram's method. Plate cultures show bacilli, cocci, diplococci ; the last not decolorized by Gram's method.

Case II.—Urine-agar sterilized urine. Male, aged twenty-one. Gonorrhœa, three months' duration. First attack ; treatment internal and local. Cover-glass from plate culture shows cocci and diplococci not decolorized by Gram's method.

Case III.—Culture-agar and sterilized urine. Male, aged twenty-four. Gonorrhœa, four weeks' standing. First attack ; treatment internal only, no local. Plate culture, same results as above.

Case IV.—Sterile urine. Male, aged nineteen. Gonorrhœa, two weeks' standing. First attack ; treatment internal only. Cover-glass from urethra shows gonococcus decolorized by Gram's method. Plate cultures showed various colonies, few corresponding to those described by Wertheim. These colonies show diplococci which decolorized by Gram's method.

Case V.—Urine-agar plus sterile urine? Male, aged twenty-four. Gonorrhœa, three weeks' standing. Cover-glass from urethra shows gonococci decolorized by Gram's method. Plate cultures negative.

Case VI.—Urine sterile? Male, aged twenty-two. Two months' standing. Internal but no local treatment. Cover-glass shows gonococci decolorized by Gram's method. Plate culture shows cocci and other bacteria and diplococci, but no gonoccoci.

Case VII.—Agar plus sterile urine? Male, aged twenty-five. Gonorrhœa, three weeks' standing ; internal treatment only. Cover-glass from urethra shows gonococci decolorized by Gram's method. Plate cultures, numerous colonies, few characteristic gonococci colonies, which decolorized by Gram's method.

Case VIII.—Agar sterile urine? Male, aged twenty-two. Two weeks' standing ; second attack ; internal treatment only. Cover-glass from urethra shows gonococci decolorized by Gram's method. Plate culture negative.

The first series of experiments with urine-agar were rather discouraging to me, as I believed that the sterile urine would probably have enhanced its virtues as a medium. In this connection I must say that Dr. Alexander Lambert, of this city, kindly suggested and prepared for me Kitasato's filter as modified by him. Such a filter was attached to a Sprengel air-pump. In this manner I obtained sterile urine. For control experiment the urine was kept at body and at room temperature, but no development of bacteria followed. The urine before filtration reacted acid, specific gravity 1.021, and despite filtration its specific gravity and acidity remained unchanged, a point worthy of notice. Having then obtained sterile urine I had hopes of securing a perfect urine-agar medium, but my anticipations were not realized, inasmuch as the sterile urine did not cause gonococci to grow more abundantly, nor could I demonstrate any better growth of gonococci on plate or test-tube cultures. It is needless for me to state that I was careful to select pus as far back from the meatus as possible in order to avoid the probability of mixed bacteria. Encouraged, on the one hand, to find the gonococci on urine-agar with Petri's dishes, I was discouraged, on the other hand, that I could not employ, as Finger also admits in his article, the urine-agar as a transplantation medium. It is a deplorable fact that while we have thus an available medium for the cultivation, we have not in urine-agar a perfect transplantation medium. The property of immediate transplantation I regard as an important adjuvant in the study of the biology of the gonococcus. In this connection the medium of Bumm also Wertheim's placenta-serum agar medium, have proven of inestimable value to me.

Placenta Blood-serum.—I strictly followed the di-

* The interrogation point is used to indicate the fact that the urine employed was as near sterile as could be obtained at the time.

rections of Wertheim in the preparation of placenta blood-serum, but not in the application of it. For the purpose of obtaining placenta blood, I availed myself, through the courtesy of Dr. Tucker, of the facilities provided by the Sloane Maternity, New York. For convenience I have had the placenta blood collected in sterilized potato-culture test-tubes about one-half full. I could then easily separate after an hour or more with a sterilized thin glass rod the coagulum within the large test-tubes. After twenty-four hours' standing in the refrigerator I drew off with a sterilized pipette the expressed serum into a smaller-sized sterilized test-tube. This was allowed to stand another twenty-four hours in the refrigerator, so that the remaining red corpuscles could settle to the bottom; the straw-colored serum was then decanted into another sterilized test-tube and placed into a liquid blood-serum sterilizer, for the purpose of sterilizing the liquid blood-serum by fractional sterilization at a temperature of 65° to 68° C. for one hour on each of six consecutive days. To control the sterilized serum tubes they were placed in the incubator for forty-eight hours. The tubes containing two parts of agar were liquefied, then allowed to cool off, and placed in a water-bath at 40° C., together with tubes containing serum one part. They were then poured out in Petri's plates and then into sterilized test-tubes as the transplantation medium. Incidentally I would state that in many instances pus was kept in sterilized test-tubes and taken to the laboratory five or six hours after withdrawing it from the urethra, then it was sown on plates, and in nearly every case, twenty in all, the gonococcus (Neisser) was obtained and isolated. In sowing the pus on surface cultures I obtained a similar result, especially in fresh cases of gonorrhœa, just as Wertheim did when he diluted the secretions in the serum tubes, and then mixed them with agar and poured out the pus-inoculated medium on plates. In chronic gonorrhœa I would prefer the method described by Wertheim. Thus if gonococci are present, no matter in how small a number, we are almost certain to find some single deep or surface colonies of the gonococci. After twenty-four hours I have seen colonies of the gonococci as described by Wertheim, and was always able to transplant them into chest-serum agar test-tube cultures. That I was dealing with the gonococcus (Neisser) I will show later on, in describing my inoculation experiments.

The Gonococcus Analysis Table is as follows:

Name. Gonococcus (Neisser). (Fig. 4.)

Occurrence. Urethra, vaginal tract.

Form. Diplococci.

Grouping. Mostly Diplococci.

Size. 1–4 m. Stains with aniline dyes, best with alcoholic two per cent. methyl violet solution. Gram's stain becomes decolorized.

Relation to air. Aerobic.

Temperature. At body temperature only.

Action on Gelatin. No growth.

Milk. No growth.

Smith-tube. Gas formation, no growth.

Gelatin Puncture. No growth. Surface colonies, no growth. Deep colonies, no growth.

Gelatin Plate. No growth.

Agar Plate. No growth. Agar tubes, no growth. Puncture or surface.

Glycerin-agar Plates. No growth. Tubes, puncture or surface, no growth.

Urea-agar. No growth.

Uschinsky's Medium. No growth.

Loeffler's Coagulated Blood-serum Tubes. No growth.

Wuertz Agar. No growth.

Wuertz Agar + Placenta-serum. Whitish gray growth. Medium turned faintly red.

Rosolic Acid Broth. No growth.

Meat Broth. No growth.

Potato. No growth.

Acid-gelatin Plate. No growth.

Tube Puncture Surface. No growth.

Gelatin-gelose Plates. No growth.

G. G. Tubes. No growth.

Urine-Agar Plate. Slight growth, corresponding to description which I propose to give on blood-serum agar plates.

Urine-agar + Sterile Urine. Slight growth.

Urine-agar + Urine Filtered. Slight growth.

Urine-agar Test-tubes. Surface slight growth. Puncture no growth.

Acid-gelatin + Placenta Serum. No growth.

Gelatin-gelose + Placenta Serum. No growth.

Glycerin-agar + Placenta Serum. Slight growth on surface.

Two per cent. Agar + Sheep-serum. Plates, slight growth.

Tubes. Surface slight growth.

Two per cent. Agar minus Salt + Sterilized Placenta Serum. Slight growth. Tube, surface slight growth.

Two per cent. Agar minus Salt + Chest-serum. Plates abundant growth. (Fig. 5.) Colonies shape circular. Edge somewhat irregular. Shading off into yellow-white. Texture finely granular in periphery. Color yellowish. Presents punctated spots of higher refraction in and around centre, chest-serum agar tube more abundant than on placenta, sheep-serum, or ascites fluid. Appearance, grayish-white. Puncture growth, grayish-white appearance.

Two per cent. Agar minus Salt + Filtered Chest-serum Plates. Considerable growth. Tubes, surface growth, slight growth grayish-white appearance, serum presenting small, crystal-like bodies.

Pathogenesis, pathogenic.

Morphology.—Gonococci are found mostly in pus-cells (Fig. 8) and at times in other portions of the field, a fact probably due to the mechanical effect of smearing the pus on cover-glass or slide. They appear generally in pus-cells, as diplococci, coffee-bean in shape, or in groups of two or four, generally extra-nuclear. In pure cultures they appear as diplococci. (Fig. 9.) At times they appear as round diplococci of various sizes, especially in older cultures. Others again are irregular in shape or granular in appearance. In this connection it must be remembered that the gonococcus possesses the peculiarity termed in bacteriology "involution form" in older cultures.

In my cultures of chest-serum agar, at the expiration of about twenty-one days this so-called "involution form" was very apparent, so much so that the micro-organism was barely recognizable as the gonococcus; nevertheless in transplanting this culture I obtained a gonococcus growth on chest-serum agar. A culture sixty-two days old, and a second one hundred and two days old, showed in cover-glass preparation nothing resembling a gonococcus. All that could be seen was a granular mass which by Gram's method became decolorized. In view of the diversified appearance of the gonococci in older cultures under these varying conditions, opinions vary as to the longevity and virulence of the gonococcus in chronic forms of disease. From a medico-legal and social stand-point the practical bearing of this matter is very evident. Thus candidates for marriage who are victims of a chronic urethritis and who seek advice in regard to the advisability of their contemplated marriage can only receive an affirmative opinion, providing a thorough clinical and bacteriological examination of the secretions are executed in the following manner:

Cover-glass preparation on three consecutive days must be examined with a microscope provided with a mechanical stage and by Gram's method. Should these specimens prove negative, to exclude any possibility of doubt, cultures should be made on chest-serum agar on three consecutive days, and for such an important examination I would not recommend a surface culture

but a series of diluted chest-serum test-tube inoculations as described by Wertheim.*

The Gonococcus as Found in the Human Economy.—Up to date a perusal of the literature of the subject brings to light the fact that gonococci are reputed to have been found in the following regions and in about the following order of frequency: Male urethra, vulvo-vaginal tract, vesical bladder, eye, peri-urethral abscesses, glands of Bartholini, joint effusions, kidney, Fallopian tubes, peritoneum, rectum, and mouth.

The Staining of the Gonococcus by Aniline Dyes.—Of the various dyes used—Bismarck brown, safranin, methylene blue, fuchsin, gentian-violet, and malachite-green—I found that fuchsin and gentian-violet are faulty in that they stain too intensely. Success with the use of these dyes depends, no doubt, upon the skill with which a thin film is smeared on the glass. As the best method for ordinary staining I would recommend a two per cent. alcoholic methyl-violet solution. This is practically a differential stain, and consumes but thirty seconds in its execution. As a practical double stain, I employed Schütz's[14] and Lanz's[11] methods.

Having thus passed in review the various methods commonly employed for the detection of the gonococcus and for its differentiation stain, I am forced to the conclusion that any procedure which does not include Gram's[15] method is imperfect and unreliable. His method is the only reliable one for the differentiation of the gonococcus from all other diplococci found in the healthy urethra and vulvo-vaginal tract. So careful an observer as Friedlander goes further and states it is the ideal method of staining bacteria. In looking over the literature of Gram's stain, I find that a great many writers obtained different results with it. This, to my mind, is not surprising on account of finding in our text-books on bacteriology descriptions which differ materially from each other. Those of you who are interested in this particular theme can readily become convinced of the correctness of this statement by looking up any of the following authors: Crookshank, Flügge, Fraenkel, Günther, Heim, Sternberg, Hueppe, Von Jacksch, O. Israel, etc. E. C. Wendt,[16] New York, credits Roux[17] with having first found that the gonococcus becomes decolorized by Gram's method. Gram in 1884 gave us an excellent description of his method. This stain was accidentally discovered by him while engaged with aniline gentian-violet sections that were placed in iodine solutions. This led him to study the subject more in detail, with the result that he gave us an excellent method for staining bacteria in sections and cover-glass preparation. In the preparation of the aniline gentian-violet solution Gram refers us to Friedlander's book, and out of the many solutions found therein I have selected the Koch, Ehrlich, aniline-water, gentian-violet solution, as the best for illustration. I have prepared it as follows: To 10 c.c. of water add 2 c.c. of aniline oil, shake well and filter through moist filter-paper. To the clear aniline-water obtained add 1 c.c. of ninety-seven per cent. alcohol and 1 c.c. of a concentrated alcoholic gentian-violet solution. I have given these proportions, as this is about the quantity required for ordinary staining. After passing the cover-glass quickly through the flame, it is then placed in this solution from two to three minutes. Gram next advises that the cover-glass may be washed in alcohol or not. I preferred to drain off the excess on filter-paper without washing in alcohol. The cover-glass is then placed for five minutes in Gram's iodine solution, which consists of iodine, 1 part; iodide of potash, 2 parts; water, 300 parts, and then placed directly into alcohol ninety-seven per cent. in order to wash out all the coloring matter. It is sometimes advisable to renew the alcohol. Now wash the cover-glass well in water and place it in a Bismarck-brown solution, which consists of a concentrated aqueous Bismarck-brown solution, 1 part; water, 5 parts, for one or two minutes, then wash in water and mount in balsam. For differential stain, instead of Bismarck brown I have employed fuchsin and safranin, only to find that the Bismarck brown gave the best results. It is to be regretted that we have not at present a specific stain for the gonococcus, as we have for the tubercle bacillus.

Description of the Various Culture Media Employed for the Gonococcus.—In 1885 Bumm first successfully cultivated the gonococcus, using a mixture of beef and human blood-serum. Then Wertheim employed the placenta blood-serum described by me above. My charts have shown that of all media used for cultivation, the chest-serum agar gives the most abundant growth of the gonococcus. Various other fluids of the human body have been employed by different investigators with varying results—peritoneum serum, chronic synovitis effusions, hydrocele and pericardial fluids, the fluid contents of ovarian cysts, and hydrosalpinx fluid. I have employed placenta serum, sheep blood-serum, peritoneum serum, filtered chest-serum, and found that liquid sterilized chest-serum plus two per cent. agar broth plus one per cent. peptone with or without one-half per cent. salt, gave me the best results. This fact I could attribute only to the great amount of serum albumin found in chest-serum. The value of this serum can be demonstrated by placing a flask containing chest-serum in a refrigerator, allowing it to stand over-night, when we will find a clot has been formed and that the supernatant serum appears to be of a more tenacious consistency than placenta, peritoneum, and beef serum, when treated in the same way. I strictly controlled my experiments with plate and test-tube cultures by mixing sterile beef-serum with two per cent. agar, sterile peritoneum serum plus two per cent. agar, beef-serum plus two per cent. agar, placenta serum plus two per cent. agar, chest-serum plus two per cent. agar, and found that of all these chest-serum plus two per cent. agar, etc., showed the most abundant growth of the gonococcus in plate and in test-tube cultures. One of the plates will show almost a pure gonococcus culture obtained from urethral pus. (Fig. 10.) The chest-serum was obtained in one case from a patient suffering with hydrothorax, with a temperature of 38.3° C. In another case, from a patient suffering from an acute pleuritis, with a temperature of 39.5° C. From each case one litre was withdrawn.* I rarely found it necessary to pour the supernatant chest-serum into another test-tube, as is done in placenta serum, owing to the number of red blood-corpuscles present in the latter serum. Not being satisfied with these results and desiring to avoid the long and tedious fractional sterilization of liquid serum, I was anxious to obtain a method of obtaining sterile serum, as I obtained sterile urine. I therefore resorted to the filtration method. I found chest-serum on account of its tenacity difficult of filtration. At the rate of six hours per day for one week, using Reichel's filter with the aid of Sprengel's air-pump, only 200 gm. of filtered chest-serum were obtained. In order to render the chest-serum more liquid, I first filtered it through sterilized absorbent cotton, placed in a sterilized glass funnel, but this gave about the same result. The only advantage derived from the filtered sterile serum was its extremely clear appearance. For the cultivation of the gonococcus, however, in plate and in test-tubes, it gave a less abundant growth than the sterilized chest-serum and gave a result about equal to that of placenta-serum agar.

In my efforts to procure sterile serum I followed the suggestion of Dr. Prudden, namely, to add to the chest and peritoneum serum kept in sealed flasks and test-tubes one-half per cent. or one per cent. of

* It would be advisable to produce an artificial urethritis with a nitrate of silver solution for the purpose of bringing gonococci to the surface.

* To Dr. Ewing I am indebted for supplying me with chest and peritoneum serum.

chloroform. Before adding chloroform, control experiments were made in the following way: a half dozen test-tubes containing peritoneum serum were left uncorked and exposed to the air for forty-eight hours; a second half dozen containing peritoneum serum were at once sealed after one per cent. or one-half per cent. chloroform was added. At the end of forty-eight hours chloroform was added to the uncorked tubes, which were then sealed. Thirty days later a great number of bacteria were nevertheless found in the half dozen test-tubes that were at first left exposed to the air. Among the second half dozen test-tubes were a few containing no bacteria. These were treated with agar, peptone, and salt, and could be used as a culture medium, notwithstanding the addition of the chloroform. I regret to say that I could not complete these experiments for this publication.

Studies in the Normal Vulvo-vaginal Tract in Children.—In looking over the literature on this subject, I found that little has been written. The most frequent allusions to this topic is in connection with the vulvo-vaginal tract during pregnancy. Döderlein [18] examined the lochial discharges and found that, where the lochia were profuse, staphylococci and streptococci were abundant. Krönig [19] also found streptococci and staphylococci and believed that the streptococci become non-virulent owing to the hyperacidity of the vaginal secretions. G. Thomen [20] found in three out of seven cases of lochial discharge streptococci, although none could be demonstrated in the vagina and cervix. My investigations in connection with the normal vulva were principally made for the same purpose as those in the normal male urethra—that is, I endeavored to ascertain various kinds of bacteria which cover-glass preparations and ordinary culture media bring to light. I also studied the vulvo-vaginal secretions and urethra of children, employing media upon which the gonococcus thrives. Out of twenty cases examined in this manner, in no single instance have I been able to demonstrate the gonococcus (Neisser). Cover-glass preparations showed epithelial cells, and in some cases quite a number of pus-cells, numerous bacteria, cocci, diplococci, short bacilli, large pear-shaped bacilli with possible spore formation (?), smegma bacilli, and spirilla. The age of the children examined varied between three months and thirteen years. The secretions were taken from all parts of the vulva, without cleansing the parts at all. Whenever urethral discharge was taken the vulva was cleansed with water. I have met a class of cases with very slight muco-purulent discharge which the parents were not aware of. Then again there were other cases whose only symptom was enuresis. This latter class of children attracted my attention especially, as they turned out to be simply a catarrhal colpitis, clinically and microscopically. Cover-glass preparations showed a great number of pus-cells, containing diplococci, partly resembling in size and form the gonococcus (Neisser), also small cocci and numerous other bacteria. (Fig. 11.) These diplococci were found independently of the methods of Bockhart, E. Fränkel, Koplik, and others. This fact led me to believe that if there was such a micro-organism as a pseudo-gonococcus, the diplococci of the vulva, found in the pus-cells and partly resembling the gonococcus, these certainly would deserve the denomination.

I believe that the term pseudo-gonococcus as at present applied is apt to mislead. It would be wiser to term the micro-organism found in the pus-cell of the catarrhal form of colpitis, diplococcus colpitis catarrhalis. Whether this micro-organism is pathogenic and infectious, I am not prepared to state at present. After I had examined the discharges of my catarrhal colpitis cases which clinically did not appear as gonorrhœal cases and obtained negative results, I came to the conclusion that these cases of colpitis must be attributable either to the diplococcus found and isolated by Bockhart or to causes as yet unknown. The best proof of the correctness of this assertion is the fact that these diplococci found in the pus-cells, which partly resemble the gonococcus, will not decolorize by Gram's method, as my plates and slides will show. Bockhart in 1886 gave a thorough description of a small diplococcus found in the vagina and proved it to be the origin of non-specific urethritis. He was able to secure a fair growth of these small diplococci on agar plates and a more abundant growth on blood-serum at body temperature. His inoculation experiments with the small diplococcus in the human urethra gave a positive result. He produced an artificial urethritis, the secretions of which showed the small diplococci in pus-cells. E. Fränkel [21] describes cases of endemic infectious colpitis which I believe to be analogous to Bockhart's. E. Fränkel inoculated the eyes of rabbits with secretions from catarrhal colpitis cases, with negative results. His inoculation on the human eye gave a positive result. In one out of three inoculations he observed on the fifth day a catarrhal condition of the eye, the secretion from which gave the same diplococci as those in the secretions of the vagina. He does not mention the Gram stain at all for cover-glass preparations, except as applied to sections, and even then found no bacteria. In a later announcement he describes experiments in trying to isolate this diplococcus. He obtained several forms of diplococci described by Bumm, and a diplococcus not described by Bumm, with which he inoculated the human eye with negative results. On one occasion he produced in his inoculation experiments a purulent conjunctivitis in a rabbit which lasted five days, but could not find the characteristic diplococcus on account of the prevalence, as he claimed, of other bacteria. This experiment of E. Fränkel would appear fallacious, owing to the fact that secretions and not pure cultures were employed. E. Fränkel considers his diplococcus to be the real gonococcus, only modified in its behavior from its successive growths. My attention was specially directed to a diplococcus found in the catarrhal form of colpitis. This micro-organism simulated in appearance the one found in the pus-cell of the secretions of catarrhal colpitis. I studied the biology of this diplococcus, as my table will show. (Fig. 6.)

DIPLOCOCCUS.

Occurrence. In catarrhal form of colpitis of children.
Form. Diplococci and cocci.
Grouping. Diplococci and cocci.
Size. About size gonococcus, 1 to 4 micro-millimetres.
Color. None.
Temperature. Room and body.
Relation to Air. Aerobic.
Gelatin Plates. Colony.
Shape. Circular and elliptic.
Size. From 3 to 5 micro-millimetres.
Edge. Sharply defined.
Texture. Coarsely granular.
Color. Yellowish brown refraction.
Gelatin Tubes. Slight surface growth, whitish appearance. Did not liquefy. The same in puncture. Acid-gelatin plate. Texture finely granular, otherwise the same as in nutrient gelatin plate. Acid-gelatin surface, slight whitish growth not liquefying, the same in puncture.
Nutrient agar plates.
Colony. Shape circular. (Fig. 7.)
Size. 3 to 5 mm.
Edge. Sharply defined, regular.
Texture. Granular.
Color. Yellowish.
Nutrient Agar Tubes. Abundantgrowth, pale yellow.
Glycerine Agar Tubes. Slight surface growth, whitish gray.
Urea Agar. Surface culture and puncture, no growth.

Chest-serum. Flocculer deposits; medium clear.

Potato. Yellowish growth; slightly spreading.

Milk. Some white sediment; reaction acid; not coagulated.

Fermentation Broth. Growth in both arms but cloudy in long arm; white deposit; slight pellicle.

Uschkinsky's Medium. Slight growth; clear.

Wuertz's Agar. Abundant growth on surface medium; becomes blue above; lower part unchanged; alkaline; the same in puncture.

Pathogenesis. Negative in one case in the normal male urethra.

Vulvo-vaginitis of Children.—Vulvo-vaginitis, urogenital blenorrhœa, or colpitis gonorrhoica in its various forms must have been just as prevalent years ago as it is to-day, only that its nature and causation were less understood. Little was mentioned of this condition in the medical works of the day. Thus in such old works as that of Adolph Henecke,[22] 1821, and that of C. M. Billiard,[23] 1850, no mention whatever is made of vulvo-vaginitis. Mr. Bouchut[24] in 1855 does not mention anything of vulvo-vaginitis. Dr. W. H. Day[25] in 1881 describes discharges of a muco-purulent character during dentition from intestinal irritations, ascarides in the rectum after scarlet fever and other fevers, but does not mention its identity with gonorrhœa. Vogel[26] in 1887 describes catarrhal and gonorrhœal forms of vulvo-vaginitis. Ashby and Wright,[27] 1889, speak of vulvo-vaginitis and state it is due to neglect, dirt, irritation by thread-worms, and at times the result of contact with the discharges from vulvitis. J. Lewis Smith[28] in 1890 speaks of a catarrhal and gonorrhœal variety. In Keating's Encyclopedia,[29] 1890, vulvo-vaginitis is considered in two varieties; first, a simple catarrh due to dirt, irritation, etc., and the infectious varieties due to the gonococcus. Henoch[30] in 1892 described an infectious form, but states that he attaches little importance to such gonorrhœal secretions for the reason that gonococci can be demonstrated in cases of vulvo-vaginitis, in which no history of gonorrhœa can be proven. Baginsky[31] in 1892 describes a vulvo-vaginitis due to mechanical irritation or to worms; second, vulvo-vaginitis catarrhalis et blenorrhoica caused by the same factors, and also mentions an endemic form of vulvo-vaginitis due to an organism similar to the gonococcus, or depending upon the gonococcus. I can indorse his opinion. I have found the true gonococcus and another diplococcus in pus-cells in one and the same specimen, the true gonococcus showing the decolorization by Gram's method, the other diplococcus in the pus-cells partly resembling the gonococcus, retaining the aniline gentian-violet stain. Baginsky also describes other varieties of vulvo-vaginitis. Starr,[32] 1894, divided vulvo-vaginitis into a catarrhal or irritative and a gonorrhœal form.

On reviewing the literature on the clinical and bacteriological studies of vulvo-vaginitis, I find as early as 1878, in an article written by J. Morris,[33] that mention is made of the fact that girls have been infected through the agency of clothes, and of the difficulty of differentiating the specific from the non-specific variety. Neisser[34] states that fluor vaginæ is due to the gonococcus and that ordinary vaginal secretions contain all forms of bacteria, except gonococci. Pott[35] regards purulent vaginitis to be of specific origin and gives other causes. Cseri[36] found the two varieties of diplococci in pus, and claims that the one variety is identical with E. Fränkel's diplococci. He cites, however, no culture experiments. Dusch[37] reports an epidemic of vulvo-vaginitis in hospital practice, and speaks of the possible infection by the use of the same thermometers, chambers, toys, etc. Hofmokl[38] speaks of a spontaneous occurrence of vulvo-vaginitis, and as special etiological factors cites malnutrition, scrofulous, tuberculous, rachitic, and specific affections, scarlet fever, measles, scabies, masturbation, oxyuris-vermicularis, and states that he has observed the same trouble in apparently healthy children. He rarely observed the gonorrhœal type, and gives the age of occurrence between eight and twelve years. No microscopical examinations were made by him. Spaeth[39] reports vulvo-vaginitis cases to be of gonorrhœal origin. No cultures were made by him. R. Skutsch[40] cites the case of two hundred and thirty-six school-girls who were attacked with vulvo-vaginitis after bathing. Some of these girls were afterward affected with ophthalmia blennorrhoica.

Epstein[41] gives no etiological data for catarrhal vulvitis except uncleanliness, and uses the term "desquamative catarrh." Cassel[42] gives accurate clinical and microscopical descriptions of cases, but he does not state that he employed culture media. Martin[43] claims that the differentiation between gonococci and other diplococci found in pus-cells must be still considered impossible. In refutation, so far as my experiments go, they seem to prove that this matter of differentiation of the various diplococci is not *sub judice*, but a certainty by the aid of Gram's method. The inoculation experiments of Martin in the male urethra are open to the serious objection that he did not avail himself of a pure culture but simply of the secretions. Koplik[44] describes a diplococcus found in the pus-cells of the secretions of diseased vulvo-vaginæ of children. He enumerates three varieties of vulvo-vaginitis, viz.: that due to uncleanliness, manifesting itself by painful micturition and a slight serous discharge; second, a catarrhal type with slight purulent discharge; and, third, a true gonorrhœa. E. Berggrün[45] examined bacteriologically thirty-one cases of vulgo-vaginitis, eleven of which gave positive results on cover-glass preparations and on blood-serum agar; Berggrün himself admitting, in the case of catarrhal type of vulvo-vaginitis, his inability to ascribe a reason for this. He divides his purulent cases first into a specific type; second, a type due to trauma, and third, a catarrhal form which he believes to be infectious.

Experiments on the Vulvo-vaginal Tract of Children.—It is a notorious fact that in many instances the etiology of vulvo-vaginitis of children is shrouded in an atmosphere of obscurity. There is, however, another class of cases in which the etiological factor can be readily ascertained to be a direct infection from adult to child. The endemic variety originates at times in hospitals. Many cases that came under my observation at my clinic in the Mount Sinai Hospital Dispensary gave such a history of origin. These patients, it was also ascertained, presented on closer inquiry no symptoms referable to the vulvo-vaginal tract, on their admission into the hospital, where the infection took place. An important truism derived from the knowledge is that in isolation we have a preventive for the spread of vulvo-vaginitis. I believe the law which makes it compulsory to isolate such infectious diseases as diphtheria, scarlet fever, etc., would be just as applicable to cases of vulvo-vaginitis. The consensus of opinion seems to be unanimous on this point, that stuprum or direct contact, bedding, bath-tubs, thermometers, clothing, toys, chambers, closets, instruments, etc., are carriers of the poison of the disease. It is to be regretted that up to date no perfect classification of the various types of vulvo-vaginitis is extant. The classifications hitherto offered for acceptance are, as a rule, mixed types. I take the liberty of offering the following: First, a catarrhal form, subdivided (*a*) into those due to uncleanliness, foreign bodies, and trauma; (*b*) infectious, but not gonorrhœal. Second, (*a*) a gonorrhœal type, due to gonococcus (Neisser); (*b*) the mixed infection due to gonorrhœa and possibly other diplococci. I shall not utilize as statistical material results of my former examinations of the discharges from the vulvo-vagina, for the reason that I did not employ the Gram stain. In my last set of cases I always confirmed the presence of the gonococcus by Gram's method not only in cover-glass preparation,

but also in culture media. *En passant*, I shall give the history of a few striking and convincing cases.

Case I.—Aged twenty-two months, presented a purulent vaginal discharge of fifteen days' standing. Was treated locally. Father of the child had gonorrhœa of three weeks' standing, with profuse discharge, and stated that he and the child occupied the same bed. Cover-glass preparation from secretion of father and child showed gonococci decolorized by Gram's method. Chest-serum agar plates employed in the case of father and child revealed gonococci, which I could readily isolate.

Case II.—Aged two and a half; five days' duration; no treatment. Mother and father both had discharges. Cover-glass of mother and child revealed gonococci, decolorized by Gram's method.

These two cases prove almost conclusively that the gonococcus is the etiological factor.

Case III. has been of special interest to me on account of the long duration of the discharge. The child was three years old, and presented uro-genital blenorrhœa of ten months' standing. At times there was an acute exacerbation. The cover-glass shows two kinds of diplococci, first the gonococcus which decolorized by Gram's method, and second, diplococci in pus-cells which appear somewhat larger than the gonococci, but were not decolorized by Gram's method. In the latter class of cases the question would naturally arise whether we were not dealing with a mixed infection. The biology and pathogenesis of the gonococcus of the vulvo-vagina is identical with the gonococcus of the male urethra, as my culture and inoculation experiments will show. The fact that vulvo-vaginitis is so little amenable to treatment by ordinary methods is partly proof that we are dealing with the same infection as in male gonorrhœa.

Inoculation Experiments.—The first thought that occurs to our minds is whether absolute reliability can be placed in the results obtained from cultivating the gonococcus on such media as agar, potato, gelatin, nutrient gelatin, and acid-gelatin. In the first place the conditions under which the experiments were conducted by different workers were not always the same, the personal equation always entering as an important factor. Thus various investigators may view the same microscopic field, and yet the interpretations of their conceptions may be as numerous as the investigators themselves. In the case of the gonococcus this rule applies with double weight, since there is a deplorable scarcity of media available for the cultivation of this diplococcus. There are, however, other specific bacteria to which this rule does not apply at all. Thus, through the efforts of bacteriologists we are in a position to-day to differentiate a number of organisms through their characteristic growth on special media. The *bacterum coli commune*, for instance, is an acid-producer, while the typhoid bacillus is not. The crucial test for the establishment of the gonococcus on a true bacteriological basis is inoculation experiments in the human economy, since animals are to a certain extent refractory. And yet how seldom this method has been brought into play in connection with works of others becomes apparent when we look up the literature of this special topic. For we then learn that such careful investigators as Bockhart, Oppenheimer,[46] and Kreis [47] did not make inoculation experiments. Their results are therefore considered questionable by Finger and Wertheim. Sternberg [48] in 1884 thought he was dealing with the gonococcus, and yet when he came to his inoculation experiments found he was not dealing with the gonococcus at all. Recognizing the importance of inoculation experiments, my attention and experiments were principally directed to that field in order to establish the true pathological significance of the gonococcus Neisser.

It becomes my pleasant duty here to acknowledge my sincere appreciation and a sense of deep obligation to Dr. Ira Van Giesen for his painstaking efforts to further my researches by obtaining material for my inoculation experiments. He was kind enough to control my first inoculation experiments and was of service to me in many other ways. Having obtained a supposed pure culture of the gonococcus, I utilized a fifth generation on chest-serum agar. The culture in question was made from pus obtained from the male urethra.

Case I.—The patient selected, a boy aged four, suffered from idiocy, complicating chronic epilepsy. He was badly nourished. Pulse, 84; respiration, 18; temperature, 37.1° C. Having cleansed his glans penis, a sterilized platinum hook was passed into the urethra to obtain secretion for the cover-glass preparation. The specimen showed epithelial cells containing bacteria, none of which decolorized by Gram's method. To further control the urethra, plate-cultures on nutrient gelatin, nutrient agar, and chest-serum agar were made. The usual forms of urethral bacteria were obtained, none of them, however, decolorized by Gram's method. The urethra was then inoculated with a supposed pure culture of the gonococcus. Nothing was noticed up to the fifth day. In the presence of Drs. J. J. Collie and J. R. Knapp I was able to express from the urethra a drop of pus. Cover-glass preparations were made which showed pus-cells containing typical gonococci decolorized by Gram's method. To complete the experiments plate-cultures were made on chest-serum agar, nutrient agar and gelatin. I was agreeably surprised to obtain on chest-serum agar the same growth which previously was considered to be the gonococcus (Neisser), and was also able to isolate it in pure culture. The subsequent course of the disease was a mild one, the temperature (rectal) never rising above 37.7° C. On the twelfth day a very appreciable quantity of pus could be expressed. Cover-glass preparation showed quite a number of typical gonococci in pus-cells, decolorized by Gram's method. On the nineteenth day the same condition was found. On the twenty-fifth day the quantity of pus was profuse. Temperature, 37.4° C.; pulse, 120; respiration, 30. Cover-glass preparation showed numerous diplococci decolorized by Gram's method. Having thus convinced myself of the specificity of the gonococcus of the male urethra I was tempted to repeat the experiment with the supposed gonococcus obtained from vulvo-vaginitis of children. For this purpose I therefore selected a fourth generation. The case selected was an idiotic boy, aged sixteen, who had been under observation for about four years. No history of ever having had a discharge from the urethra; otherwise healthy. On the day of inoculation the temperature, 38.5° C.; respiration, 28; pulse, 120. The same precautions were observed as in the other case. Cover-glass preparation showed epithelial cells, no bacteria. Plate-cultures were taken on gelatin, agar, and chest-serum agar. The gelatin plate gave negative results, the agar plates developed a coccus not decolorized by Gram's method, and the chest-serum agar plate showed cocci and streptococci in great abundance, but not decolorized by Gram's method. With a sterilized platinum hook a pure culture of the gonococcus of vulvo-vaginitis from chest-serum agar was inoculated; the precaution was taken to have the patient empty his bladder before the inoculation. On the second day pus appeared. On the fourth day the patient presented a swollen penis, with a profuse discharge. Temperature, 38° C.; respiration, 21; pulse, 126. The temperature in this case was reduced 1° C., but the pulse increased from 120 on the day of inoculation to 126. Cover-glass preparation showed typical gonococcus decolorized by Gram's method, and from the urethral discharge I was again able to cultivate and isolate the gonococcus (Neisser).

Case II.—Adult, aged twenty-six, in the last stage of tuberculosis. Has been under observation for two years; denied any gonorrhœal history. Temperature,

40.2° C.; pulse, 150; respiration, 36. The hyperpyrexia in this case made it of special interest, as Finger claims that inoculation experiments showed only in subjects with nearly normal temperatures. Cover-glass preparation of Case II., as well as gelatin, agar, and chest-serum agar plates, showed numerous bacteria, not decolorized by Gram's method. A pure culture of the gonococcus obtained from vulvo-vaginitis was inoculated into the urethra. On the second day no discharge was present, and patient did not complain of painful micturition. Temperature, respiration, and pulse about the same. On the fourth day a slight discharge was noticed. Temperature, 39.2° C.; respiration, 30; pulse, 150. Patient felt no ill effects. Cover-glass preparation showed characteristic gonococci decolorized by Gram's method. In this case I was able also to cultivate the gonococcus from the urethra and isolate it in pure culture. On the ninth day cover-glass showed the same results as on the other days. Discharge was never profuse at any time. After death of patient, which occurred on the fourteenth day after inoculation, Dr. Van Giesen made a post-mortem examination of the genital tract. He will report the results of the examination.

Inoculation of the Large Diplococcus Found in the Normal Urethra.—In order to prove its non-pathogenic nature I utilized a pure culture of the eighth generation. The young man who was the subject of this experiment was seventeen years of age, and positively denied any gonorrhœal history. His urine before inoculation was clear; gelatin, agar, and chest-serum agar showed no gonococcus. Patient was instructed not to pass any urine for the next five or six hours. Dr. Goldenberg was a witness to this experiment. At the expiration of five days his urine was examined, but with negative results; pathologically nothing could be demonstrated.

I next endeavored to ascertain whether this diplococcus found in the catarrhal variety of colpitis is the cause of the infection. My inoculation experiments soon demonstrated that the diplococcus which I isolated from catarrhal colpitis cases is not responsible for this pathological condition of the catarrhal form of colpitis. For this experiment I selected an adult aged twenty-five, apparently in good health. Examinations of his urethra by means of cover-glass specimens and gelatin, agar, and chest-serum agar plates showed no gonococcus. A pure culture of the third generation of the diplococcus was inoculated with negative results.

Inoculation Experiments with the Diplococcus Urethræ (Turro).—Believing that Turro's supposed gonococcus had its virulence increased on an acid medium, I inoculated this diplococcus (Turro), fourth generation, from an acid-gelatin medium into a healthy male urethra, as was proven by cover-glass preparations and gelatin, agar, and chest-serum agar plates, showing no gonococci. The result of this experiment was negative.

Animal Experiments.—Various species of animals were inoculated with the true gonococcus (Neisser) with different results. Neisser, as early as 1882, had inoculated dogs with negative results. Loeffler and Leistikow[49] inoculated the abraded conjunctiva and urethra of rabbits and guinea-pigs with negative results. F. Krause[50] inoculated rabbits, cats, pigeons, and mice. Wertheim, on the contrary, claims to have produced a slight peritonitis on mice, guinea-pigs, rabbits, and rats. Finger, in his experiments on dogs, claims he produced an acute inflammation of the knee-joint of the dog by injecting a pure culture from serum agar. He, however, obtained no reaction in the urethra or rectum of the dog by injecting the gonococcus. His experiments on the peritoneum of white mice were reported as negative. The varying results of different experimenters led me to study the effect of the true gonococcus on white mice. Two healthy mice were selected. The abdominal surface was disinfected with five per cent. carbolic solution. A pure culture of the gonococcus was previously placed in 1 c.c. of sterilized distilled water. The apparatus for injection used was the one described by Petri. A half cubic centimetre of the pure culture of the gonococcus was then injected into the peritoneal cavity. Twenty-four hours after inoculation no ill effects observed; mice eat well and appear healthy. After forty-eight hours a dissection of one of the mice was made under control of Dr. Cheesman. Macroscopically no pathological changes could be demonstrated. Cover-glass preparations and chest-serum agar plates were made; the plates gave negative results; cover-glass specimens, however, showed a number of pus-cells with small masses of cocci which decolorized by Gram's method. To account for this we may assume that the cocci found were still the remains of the inoculation. On the other hand, again, the presence of the pus-cells may have been the starting-point of a beginning peritonitis. I concluded to keep the other mouse alive for several days for further investigation. On the seventh day the second mouse was dissected, and the macroscopic appearance was the same as in the first mouse. Cover-glass preparation showed no pus-cells, and sowing on peritoneum and chest-serum agar plates gave negative results.

Experiments on Dog with the Gonococcus (Neisser).—I have inoculated both eyes and the urethra of the dog with absolutely negative results. In all my experiments I was careful to transplant my cultures for the purpose of ascertaining their viability. This, then, is a summary of my experiments and studies with micro-organisms of the normal and pathological male urethra and vulvo-vaginal tract of children. While my results have tallied in many respects with those of other writers, I have frequently found it necessary to antagonize, as you are now aware, their views and conclusions. To summarize briefly, I will submit the following conclusions:

1. I believe that the gonococcus (Neisser) is never present in the normal urethra, as far as my experiments have shown.

2. The diplococci found in the normal urethra can positively be differentiated by the Gram stain.

3. I believe that the diplococcus described by Turro in connection with his acid media experiments is not the gonococcus.

4. I indorse Wertheim's conclusions, except that I believe the liquid sterilized chest-serum is a better culture medium in every way than placenta serum.

5. I believe that urine-agar is not an ideal culture medium, as Finger claims.

6. Gram's stain is the only crucial staining test for the presence of the gonococcus (Neisser), and should therefore be employed in all cases.

7. For ordinary staining of the gonococcus I would recommend a two per cent. alcoholic methyl-violet solution.

8. Certain reports of the discovery of the gonococcus in various parts of the body, such as mouth, rectum, and serous cavities, must be looked upon with scepticism, owing to the fact that Gram's stain and culture media were not applied.

9. The normal vulvo-vaginal tract is never a habitat for the gonococcus, as far as my experiments have demonstrated.

10. Gram's stain is here also the differential stain between the diplococci found in pus-cells from the diseased vulvo-vaginal tract.

11. There is reason to believe that there is a specific micro-organism in catarrhal colpitis, either the diplococcus of Bockhart or of E. Fränkel.

12. In specific colpitis the gonococcus found is identical with the one found in specific male urethritis.

13. My inoculation experiments on the human urethra confirm the belief in the specific pathogenic power of the gonococcus (Neisser).

NOTE.—I wish to express to Drs. Prudden and Cheesman my sincerest gratitude for their kindness and many acts of courtesy extended to me during my laboratory work, and to Dr. Edward Leaming, to whom I am greatly indebted for my prints.

LEUCOMAIN POISONING.

BY B. K. RACHFORD, M.D.,

CLINICIAN TO THE CHILDREN'S CLINIC MEDICAL COLLEGE OF OHIO, CINCINNATI, O.

DURING the past eighteen months I have been trying to make an experimental investigation on the influence of paraxanthin and other uric-acid leucomains in the production of certain well-known but little understood nervous disorders. In the meantime I have published two papers[1] on this subject, one entitled "Paraxanthin as a Factor in the Etiology of Certain Obscure Nervous Conditions," the other, "Uric-acid Leucomains as Factors in the Etiology of Migraine and Kindred Nervous Diseases." Since the publication of these papers I have continued the study of this subject, and now believe that I am justified in asserting that leucomain poisoning is a very important phase of autointoxication, and that it may manifest itself in at least three distinct but closely allied clinical forms, viz.: 1. As a true migraine or leucomain headache. 2. As a migrainous epilepsy or leucomain epilepsy. 3. As a migrainous gastric neurosis or leucomain gastric neurosis.

This group of nervous disorders is among the most common, the most painful, and the most intractable to treatment of all diseases. And we know even less concerning their etiology than we do concerning their treatment. The assertion, therefore, that leucomain poisoning is an important factor in the production of these disorders is most important if true, and the evidence upon which this assertion is based is also most important if true.

In the beginning let me say a word about leucomains.[2] The uric-acid leucomains are a group of bodies closely related to uric acid, of which paraxanthin, xanthin, and gerontin are poisonous, and xantho-creatinin is a poisonous leucomain of the creatinin group. It is quite possible that all of these poisonous leucomains, as well as other unnamed poisonous leucomains, may contribute to the production of the complex of symptoms which I have here classed under leucomain poisoning; but in this study I have only attempted to show that

[1] The Medical News, Philadelphia, May and October, 1894.

[2] I am indebted to the little book of Vaughan and Novy on "Ptomains and Leucomains" for many of the facts and references used in this paper.

paraxanthin and xanthin are etiologically related to the group of nervous disorders above noted as being manifestations of leucomain poisoning. Paraxanthin is by far the most poisonous of all leucomains. Salomon thus describes paraxanthin poisoning in the mouse. If one-half milligramme of paraxanthin be introduced into the peritoneal cavity of a mouse the following symptoms will result: "The reflexes are increased to a tetanus, followed by a rigor-mortis-like contraction of the muscles; marked dyspnœa is a constant symptom, which continues till death."

Xanthin is very much less poisonous than paraxanthin, but according to Filehne it produces in the frog a decided muscular rigor and paralysis of the spinal cord. In brief, we may note the following facts concerning xanthin and paraxanthin as bearing on this research:

1. Paraxanthin and xanthin are poisonous leucomains of the uric-acid group, capable of producing the most profound nervous symptoms. They are readily soluble in water, urine, and blood.

2. Paraxanthin is found in normal urine in such small quantities that its poisonous properties are lost in dilution. Salomon found only 1.2 gm. in 1,200 litres of urine. This quantity is so minute that its presence cannot be satisfactorily demonstrated in such quantities of normal urine as can conveniently be obtained from patients. In a recent personal communication Salomon says: "Nine litres of normal urine is a very small quantity to prove the presence of paraxanthin, if one has not previously worked with larger quantities so as to master the details of the work, and very much harder would it be to prove the presence of paraxanthin in four litres of normal urine, as I know from experience. . . . I would advise that not less than ten litres of normal urine be used to demonstrate the presence of paraxanthin." My own experience is in accord with Salomon's. In previous papers I have recorded my failure to demonstrate the presence of paraxanthin when working with as little as four litres of normal urine; and since these papers were written I have made a large number of examinations of normal and other urines, and I have always failed to demonstrate the presence of paraxanthin in four litres of normal urine. Upon this evidence I have concluded that paraxanthin is present in abnormally large quantities when I can find it in less than four litres of urine. Xanthin also, as a rule, requires more than four litres of urine to demonstrate its presence, but I have frequently found small quantities of xanthin where I could not find paraxanthin in working with four litres of urine.

3. Paraxanthin and xanthin are not formed in the kidney. They are excreted from the blood by the kidneys. The presence, therefore, of large or small quantities of xanthin bodies in the urine means that these bodies were present in large or small quantities in solution in the blood previous to their elimination by the kidneys.

With the above facts in mind concerning xanthin and paraxanthin, we are better prepared to study the evidence here presented to prove the existence of a leucomain poisoning.[1]

Migraine, which has heretofore been ascribed to uric acid and many other causes, is perhaps the most common manifestation of leucomain poisoning. The form of migraine which I believe to be a leucomain headache can best be described by the report of a case.

Mrs. M——, aged thirty-five. A number of her sisters have migraine, and she has been a sufferer from the same disease since she was a child. The attacks come on every two or three weeks, sometimes oftener, and at times she has immunity from them for five or six weeks. The more severe the attacks, the longer she will be free from them. A very severe attack lasting three or four days will be followed by several weeks of immunity. Again mild attacks may occur every week with great regularity, and then be followed by a severe attack and a long period of immunity. An attack almost always occurs just before or during her menstrual period. She is perfectly well quite up to the time she is taken with an attack. She has no warning, except a sensation of burning in one cheek; this is accompanied by a vasomotor dilatation of the blood-vessels of the cheek and at times of the ear. This is followed by a typical attack of migraine, with severe headache, nausea, vomiting, and prostration. The day following the attack the patient is almost well again. The urine during an attack is scant in quantity, has a dark-red color, and contains no albumin. It always contains an excess of uric acid and a diminished quantity of urea. Urea is frequently reduced to 8 to 10 gm. and the uric acid increased to 0.45 to 0.55 gm. in 1,000 c.c. of urine. The proportion of uric acid to urea upon which Haig lays so much stress is thereby greatly increased. The urine also contains paraxanthin and xanthin in greatly increased quantities. In three litres of urine passed by this patient during and after a severe attack of migraine, I found paraxanthin. I have four or five times examined the urine of this patient passed during and after an attack, and have always found paraxanthin. In the last examination I used less than two litres of urine and obtained sufficient paraxanthin to demonstrate its presence by chemical tests, by the needle-like crystals obtained by evaporating a drop of the "final fluid," and by its physiological action on a number of mice. I have always failed to find paraxanthin in the urine of this patient passed between these attacks.

From a careful study of the urine of this and other cases of typical migraine, one of which I have previously reported, I am convinced that paraxanthin and xanthin are excreted by the kidneys in great excess during the attacks in these cases, and that they are not found in excess in the urine in the intervals between the attacks. For these reasons I believe that there are a class of cases now called migraine in which leucomain poisoning is an important etiological factor, and that these attacks may therefore not improperly be called leucomain headaches.

Migrainous epilepsy is, as I believe, another manifestation of leucomain poisoning. Clinically, this is a well-known form of disease that comes on, as a rule, during middle life, as a sequel to migrainous headaches of former years. These attacks differ somewhat in character from those of true epilepsy, and they are not, as a rule, followed by mental impairment,[1] as in true epilepsy. The history of a case will best describe this interesting form of disease.

Mrs. X——,[2] aged sixty-three, is married, and the mother of six grown children. Family history is negative, except that "one sister had some nervous heart trouble." The patient was always a hard-working woman till a few years ago, when her grown daughters took charge of all the household affairs and left her without occupation. She has always been rather stout, but of late years her hearty eating and inactive life have made her much stouter than before; she now weighs more than two hundred pounds, and spends most of the day in her easy-chair; she has quite as capacious an appetite as she has ever had, and is now, as she has always been, especially fond of meat. From her earliest remembrance to September, 1892, she suffered with periodic attacks of "sick-headache," and since this date she has not had a single characteristic sick-headache; instead of sick-headache she has had epileptoid attacks, which have continued to the present

[1] As an addendum to this paper I have given the method for separating and proving the presence of xanthin and paraxanthin.

[1] This may explain the fact that Mohammed, Julius Cæsar, and possibly Napoleon Bonaparte suffered from epilepsy without mental impairment.

[2] This is the same case as was reported in the Medical News, Philadelphia, May 26, 1895; the further history of the case is here reported.

time at about the same interval as her previous attacks of migraine.

In September, 1892, she fell in her first spell, and was carried into the house in an unconscious condition; after about thirty minutes she regained consciousness, but did not know anything about what had happened. For twelve hours after the attack she had a severe headache, which passed away, leaving her as well as usual. She continued to have attacks similar to this one at intervals of about three or four weeks. In all of these spells she became unconscious, and remained so for from twenty to forty minutes, when she would regain consciousness to find herself suffering from a severe headache, which would pass off in from twelve to twenty-four hours, leaving her quite well again. These attacks came on without apparent exciting cause, and with absolutely no warning; she feels as well, if not better than usual, just before the attack. A number of these attacks have come on in the early morning during sleep; at times the patient is seized with an attack while on her feet, and falls heavily to the floor. On one occasion she bruised her face and shoulder by a fall of this kind. The after-headache became less and less severe as time passed, until at the present time "there is almost no headache following a spell." After five or six months these epileptoid attacks were less frequent, so that five or six weeks would at times intervene between the attacks, but such a long interval was usually followed by an unusually severe attack, and not infrequently by two attacks within a few hours. In the interval between the spells the patient was quite well, except that she was somewhat mentally depressed with the certain knowledge that at the end of five or six weeks she was sure to have "another spell."

On September 18, 1893, three days after a very severe spell, she came to my office for the first time. At this visit I obtained her previous history, and prescribed phosphate of soda in teaspoonful doses after each meal. The next day I examined her urine, and found no albumin, sugar, or casts.

On January 14, 1894, the attacks had continued at intervals of from three to six weeks, but I had not been fortunate enough till this day to witness one of these attacks. On this day she had two attacks, the first one mild, the second one severe. I saw her in the second. The first attack was at 8 A.M., and occurred, as usual, without warning. It lasted from twenty to thirty minutes, and she had just regained consciousness when I reached the house. At this time she was restless, somewhat confused in mind, and complained of pain in the left shoulder; the respiration was normal, and the pulse 90, strong and regular. By this time I knew enough of the case to suspect that this mild attack would be followed by another and more severe one during the day. I therefore arranged matters so that I could reach the patient within a few minutes should she have another attack that day. At 7 P.M. the second attack occurred, and I had the good fortune to be present. This attack came on while the patient was in bed, where she had remained all day as a precautionary measure against a second attack. In the beginning of the attack the attention of the family was attracted by her peculiar, noisy breathing. She became unconscious at once, her breathing labored, her lips blue, and face congested; the arms and legs were straightened and stiffened, and remained rigid for eight or ten minutes, and then became relaxed, and remained so during the remainder of the attack; the congestion of the face soon passed off, and the lips became red again, but the heavy, noisy, irregular breathing continued for twenty or twenty-five minutes, and did not become quiet and regular until just before the patient regained consciousness. The pulse in the beginning of the attack was strong, regular, and about 85 or 90 per minute; it gradually increased in frequency till at the close of the attack, which lasted forty minutes, it was 120 per minute; all the time, however, it was strong and regular. After the attack the pulse gradually returned to the normal. The pupils were the same on both sides; they reacted to light, and were contracted till near the close of the attack, when they became normal. There were no muscular twitchings except in the right upper eyelid, and here they occurred for a short time only during the most severe part of the paroxysm. After the heavy breathing subsided the woman lay for about ten minutes apparently in a normal sleep; she then began to move, opened her eyes, was much confused, and could not understand what had happened to her. She was now very restless, complained of pain in her left shoulder, and wished to be moved frequently; she also complained of being sick at the stomach (this has been a common symptom in her recent attacks, but she has never vomited in any of them). About one hour later she went to sleep, and slept the greater portion of the night; the next day she did not feel sick, but remained in bed, and on the second day she was up and about as usual.

This attack was "just like all of her previous spells," and I have described it in detail to impress the following points, which were characteristic of all her attacks: 1, sudden onset of attack, as a rule without warning; 2, muscles rigid, but not convulsed; 3, labored, gasping, irregular breathing: 4, unconsciousness from beginning to end of the attack; 5, heart's action rapid, but regular and strong.

The urine of this patient was collected, and the quantity of uric acid and urea was carefully estimated each day, over a period of nearly three months.[1] These examinations clearly show that during these epileptoid attacks the excretion of urea is very much decreased and the excretion of uric acid is vastly increased, the proportion of uric acid to urea in the urine excreted during an attack is, therefore, very greatly increased. In other words, this case corresponds in every particular to that class of epileptoid cases which Alexander Haig describes as being due to that little understood condition, "the uric-acid diathesis."

I had collected four litres of urine passed just before, during, and following a severe attack; this urine was given to Mr. Otto Bange, a professional chemist, with the request that he would abstract from it the paraxanthin it contained. Mr. Bange found paraxanthin, the "final liquid," being evaporated down to about ½ c.c.; this paraxanthin solution was diluted with distilled water to 4 c.c., and this dilute paraxanthin solution was used for experimentation. From a drop of this solution on a glass slide characteristic needle-shaped paraxanthin crystals crystallized out. One drop of this solution in potassium hydrate solution gave the white precipitate which is characteristic of paraxanthin. The physiologic effect of this solution on mice was similar to the symptoms of paraxanthin poisoning in the mouse as described by Salomon. One minim of this paraxanthin solution was injected into the peritoneal cavity of a full-grown gray mouse at 5.45 P.M.; at 5.48 P.M. the mouse was very nervous, jumped spasmodically when the sides of the tin can were touched; this reflex excitability continued until it was almost a tetanus. At 5.50 P.M. the mouse fell in a convulsive movement, and almost immediately stiffened in a clonic tetanic contraction of all the muscles. This muscular tension was kept up almost uninterruptedly for three hours, when the mouse died. Toward the close of this period the muscles were relaxed, and except at the onset there was no convulsive movement. From the beginning to the end of the attack there was dyspnœa and a gasping respiration, which after a time was irregular.

In a number of experiments on mice and rats, of which the above is a type, it was proved that the substance extracted from the urine was certainly paraxanthin, and that it always produced a group of symptoms very similar to those from which my patient suffered

[1] See full report in Medical News, Philadelphia, May 26, 1894.

when she was excreting this paraxanthin, and Salomon writes me that these observations correspond exactly with his paraxanthin poisoning of mice.

The above observations were made previous to May, 1894, and since that time I have had this case continually under observation. The urine has been repeatedly examined both by Mr. Bange and myself, and we have always failed to find paraxanthin in three or four litres of the urine of this patient passed in the interval between the paroxysms, and have never failed to find paraxanthin in three litres of the urine passed during and just after these epileptoid attacks.

Very recently I examined three litres of urine from this patient passed during and after one of these attacks. In this examination the liquid became turbid in the final evaporation, when the fluid had been reduced to 5 c.c. The liquid was then allowed to cool and the xanthin that separated out was removed; the liquid was again evaporated and cooled to separate the xanthin, and it was then finally evaporated to ½ c.c. This "final fluid" proved to be a very concentrated solution of paraxanthin. It was diluted with distilled water to 5 c.c. of fluid, and this diluted solution of paraxanthin was used for experimentation. From the evaporation of one drop of this fluid on a glass slide there resulted a very heavy deposit of needle-shaped paraxanthin crystals, and three minims of the fluid produced characteristic paraxanthin poisoning in the rat. In the evaporation of this paraxanthin solution there crystallized out a very large amount of xanthin crystals, more than could be redissolved in 8 c.c. of distilled water at room temperature. Ten days after the attack, during which this urine was excreted, I obtained another specimen of three litres of urine, passed in the interval between the attacks, when the patient was at her best, and in this urine I failed to find even a trace of paraxanthin, and found only a small quantity of xanthin. The urine of this patient has been so frequently examined that I am safe in the assertion that during these attacks it contains paraxanthin and xanthin in enormously increased quantities.

In the study of this case of migrainous epilepsy the following summary of facts may be made:

1. Uric acid and its compounds are not poisonous.

2. Paraxanthin and xanthin are poisonous leucomains of the uric-acid group, which, when injected into mice, produce the following symptoms: *a.* Nervousness, extreme reflex excitability, almost a tetanus, and at times convulsive movements. *b.* Clonic tetanic stiffening of all the muscles, followed by muscular relaxation. *c.* Dyspnœa, orthopnœa, asphyxia. The gasping and difficult respiration is perhaps the most characteristic symptom. *d.* Stimulates the heart. Its movements are rapid and strong.

3. This patient during the interval between the attacks did not excrete sufficient paraxanthin to be detected in three litres of urine.

4. This patient during an attack excreted a quantity of paraxanthin and xanthin enormously in excess of the normal quantity. The paraxanthin thus excreted and obtained from three litres of urine produced in the mouse and rat the characteristic symptoms of paraxanthin poisoning above narrated.

5. The attacks during and after which this patient excreted such large quantities of paraxanthin were very similar in symptomatology to paraxanthin poisoning in the mouse.

6. The paraxanthin excreted in such large quantities just following these attacks must have been in solution in the blood during the paroxysm.

In the light of these facts it seems to me impossible to resist the conclusion that the attacks from which this patient suffers are due to the presence in the blood of an excess of paraxanthin and possibly other poisonous leucomains. If this be true, there is a form of epilepsy, closely allied to migraine, which should be called leucomain epilepsy. I wish here to refer to a point which I noted in a previous paper.[1] In my experiments upon mice I found that permanganate of potash was a fairly good antidote for paraxanthin poisoning, and the paraxanthin solution used in these experiments was obtained from the urine of the above leucomain epilepsy case. For this reason I decided to give my patient one grain of permanganate of potash three times a day in the hope of preventing these attacks. Under this treatment the patient had immunity from these attacks for ninety-four days; then followed a severe attack on February 11, 1895—the permanganate was continued—two weeks later she had another attack, not so severe, and from that time to the present writing (May 17, 1895), she has not had an attack. During the two years that this patient has been under observation she has been given a great variety of treatment[2] both medicinal and dietetic, but under no other treatment has she been free from these attacks for a greater period of time than six weeks. Whether the benefit that has followed the permanganate treatment in this case is a coincidence or an effect can only be discovered by subsequent observations.

Migrainous gastric neurosis is a very common disorder, occurring in both childhood and adult life. The clinical picture which it produces is well known to all clinicians; but at the present time we have as little satisfactory knowledge concerning its etiology as we have concerning its treatment. This condition, which I believe to be a leucomain gastric neurosis, is one of the most distressing of ailments, and may best be described by the report of a case.

Mrs. P——, aged thirty-four, married, and mother of three children. Her mother and a number of her family have suffered from "sick-headache." She had sick-headache when a child; these headaches continued up to about five months ago. At this time she would have headache with great regularity every week or every two weeks, and then again she would go for six weeks without having a "bad headache." These headaches would always make her very sick for one or two days, and they were always accompanied by nausea and vomiting. As a rule, the headache commenced to get better after the vomiting. These typical attacks of "sick-headache" continued up to five months ago, when they were superseded by severe attacks of gastric neurosis. The gastric attacks now come on about every two or three weeks, and are so free from headache that the patient did not in any way associate these attacks with her former sick-headache attacks, which stopped so suddenly when these attacks came on.

The clinical history of this case leaves no room for doubt but that these gastric attacks are a modification of the former sick-headache attacks.

Description of Gastric Attacks.—The day before the violent attack the patient is at times uncomfortable, with slight pain in stomach and eructation of gas; the urine is very scant and high-colored; and at times there is a red spot on left cheek, accompanied by a sensation of burning. There is much more of a warning to these than to the sick-headache attacks which preceded them. These warning symptoms may be more or less distinct, and then the attack bursts with great fury. At once the patient has very great pain in the stomach, and the vomiting comes on at the same time. These attacks are so sudden that the patient undresses and gets to bed with difficulty. The pain and vomiting continue, and a large quantity of glairy mucus is discharged from the stomach. Eructation of gas, pain in the stomach, and vomiting of mucus continue in paroxysms till they are relieved by the hypodermic injection of morphine. I have seen this patient in perhaps half a dozen of these attacks, and they do not seem to be self-limited like the sick-headache attacks, and they are only temporarily relieved by the vomiting. One of these attacks I trusted to its self-limitation; it continued for thirty-six hours

[1] Medical News, Philadelphia, November 3, 1894. [2] Ibid.

with increasing severity, and was then relieved at 3 A.M. by hypodermic injections of morphine. In this attack the patient was so exhausted that it took her eight or ten days to recover. She had much abdominal tenderness for several days and had fever of 103° F. the next day after the attack. I am thoroughly convinced that this attack would have ended fatally if it had not been relieved by morphine. In all of her subsequent attacks I have given the morphine as soon as I reached the patient. When the morphine is given soon after the beginning of the attack, the patient's suffering is very much modified. The next morning after an attack a saline cathartic is given, and after it has acted the patient is fairly convalescent, and by the second day after the attack she is almost as well as usual. When the morphine is given early in the attack there is no fever and little abdominal tenderness following the attack. These attacks are surely nervous, and do not have their origin in any morbid process going on in the stomach or intestinal canal.

The urine excreted during these attacks is diminished in quantity. It contains no albumin and no sugar. It has an increase of uric acid and a diminished quantity of urea ; but of far more importance is the fact that the quantities of paraxanthin and xanthin are enormously increased in the urine. From two litres of urine, passed during and just after one of these severe gastric attacks, I separated both paraxanthin and xanthin. The presence of the paraxanthin was proven by chemical, microscopic, and physiological investigation. The "final fluid" was in this observation evaporated to 3 c.c., and this proved to be strong in paraxanthin and xanthin. Two minims of this fluid thrown into the muscles of the back of the mouse produced death in from fifteen to thirty minutes, with the following symptoms : The mouse at first became very nervous, reflex excitability was much more marked. It jumped spasmodically whenever the wire cage was jarred with the finger. After about ten minutes the mouse held on to the wires of his cage, very much as if he were asleep ; he would loose his hold on one wire and catch the next lower down ; in this way he would helplessly slide down the side of the cage. This stupor deepened gradually, and was interrupted at times by sudden reflex spasmodic muscular contractions, which were brought out by tapping the cage. At the end of fifteen minutes the mouse fell in a convulsive movement, which was quickly followed by a stiffening of all the muscles. In this condition the mouse lay till he died, some fifteen minutes later, or about thirty minutes after the poison was given. The breathing, during all this time, was very rapid, and then became labored and irregular.

Four litres of urine passed by this patient in the interval between attacks did not show a trace of paraxanthin, and the "final fluid" evaporated to 2 c.c. was not poisonous to mice. In the mucus, etc., vomited by this patient during attacks, I have twice demonstrated the presence of xanthin, but I have not been able to find paraxanthin.

We may summarize the following interesting facts concerning this case : 1. Family history of migraine. 2. Previous personal history of sick-headache. 3. Patient now suffers from attacks of a severe gastric neurosis, which have recurred at intervals of two or three weeks, ever since the attacks of sick-headache ceased, five months ago. 4. In four litres of urine passed by this patient in the interval between these attacks no paraxanthin was found, and the "final fluid" was not poisonous to mice. 5. In two litres of urine passed by this patient during an attack both paraxanthin and xanthin were found in comparatively large quantities, and the "final fluid" was very poisonous to mice. 6. From about one pint of stomach contents vomited by this patient during an attack xanthin was separated, but no paraxanthin was found.

When we study this case in the light of these facts and in connection with the two cases previously described, it seems impossible to resist the conclusion that leucomain poisoning is a very important factor in producing these gastric attacks.

In this paper I have attempted to show that there is a very important form of auto-intoxication which may be designated leucomain poisoning ; and I have further attempted to show that we can at present recognize at least three clinical types of leucomain poisoning, viz.: *a*, Leucomain headache ; *b*, leucomain epilepsy ; *c*, leucomain gastric neurosis.

Addendum.—In the examination of the urine I now assume, for reasons given in this paper, the following propositions : 1. Four litres of normal urine is too small a quantity to determine the presence of paraxanthin. 2. Three litres of pathological urine are quite enough to determine whether paraxanthin occurs in sufficient excess in this urine to make it a probable factor in disease.

In every case at least two specimens of urine should be examined. One of three litres of urine passed during and just after the attack, supposed to be due to leucomain poisoning ; and the other of four litres of urine passed, in an interval between the attacks, when the patient is at his best.

Method (from E. Salkowski and Salomon).—The phosphates are precipitated with ammonium hydrate ; after twenty-four hours the urine is filtered or decanted from the precipitate, and a three per cent. solution of nitrate of silver is added to it ; the silver solution should be added as long as precipitation occurs. The urine is removed from the precipitate of silver compounds, and this precipitate is washed five or six times with distilled water, the water being removed each time from the precipitate by decantation. This process may require a week. The silver compounds suspended in water are now decomposed with hydrogen sulphide, the current of H_2S is made to pass through the water, in which the silver compounds are suspended, for hours ; the liquid is now filtered, to separate it from the precipitate, and evaporated down to about 50 c.c. if 3,000 c.c. of urine have been used ; the remaining uric acid is thereby separated ; this liquid being filtered, ammonia is again added ; after twenty-four hours it is again filtered and precipitated with silver nitrate, the silver being added as long as precipitation occurs ; the silver compounds are again separated from the liquid by filtration ; they are allowed to remain on the filter-paper and kept in a dark place for twenty-four or thirty-six hours ; the filter-paper holding the dry precipitate of silver compound is put in hot nitric acid of 1.1 specific gravity ; the acid dissolves the nitrates of xanthin and paraxanthin in the precipitate, and thus separates them from the nitrate of hypoxanthin, which is insoluble in nitric acid ; if working with three litres of urine, from 6 to 7 c.c. of acid should be sufficient to dissolve the xanthin and paraxanthin. After two hours the nitric acid is again heated and filtered while hot, so as to insure the solution of the xanthin and paraxanthin ; the nitric acid solution is now carefully neutralized with ammonium hydrate, and for the third time xanthin and paraxanthin are precipitated ; the precipitate is washed, suspended in water, and again decomposed with hydrogen sulphide ; this fluid is filtered while hot, and the filtrate is evaporated to 10 c.c. ; a little ammonium hydrate is now added, and after twenty-four hours the last traces of phosphates and oxalates will be precipitated ; the liquid is again evaporated on a sand-bath, and when the liquid begins to get turbid evaporation is suspended, and as the liquid cools the xanthin, if present, will separate out ; filter and again evaporate to 2 c.c. Again the liquid is allowed to cool, so that the xanthin may crystallize out, and the 2 c.c. of "final fluid" is added to 3 or 4 c.c. of distilled water, and this dilute "final fluid" is tested for paraxanthin. If this fluid contain paraxanthin—*a*, the needle-shaped crystals can be

obtained by evaporating a drop on a glass slide; *b*, the characteristic white precipitate should result when a drop of this fluid is added to a solution of potassium hydrate; *c*, a few drops of this fluid when injected hypodermically into a mouse or rat should produce the symptoms of paraxanthin poisoning.

That the crystalline mass that separated out in the final evaporations was xanthin may be proven as follows: Dissolve the supposed xanthin crystals and add picric acid, and if xanthin be present a precipitate of long white glistening crystals of picrate of xanthin will form; or a better test is to mix two or three drops of suspected xanthin solution with two or three drops of nitric acid, chemically pure, in a porcelain dish, and evaporate over flame to dryness, and a yellow precipitate results; to this yellow precipitate add ammonium hydrate and heat; if the precipitate takes on a purple color xanthin is present.

The quantity of xanthin present can be determined by carefully weighing the crystals that separate out in evaporating down to the "final fluid." But for clinical purposes this is scarcely necessary, as one can judge by the mass of crystals formed whether there be a great excess of xanthin or not. If there only be a thin layer of xanthin crystals at bottom of the final fluid, then the xanthin is not very greatly increased, but if the xanthin crystals separate out in much larger quantities, adhering to the sides of the glass vessel and forming a mass that cannot be redissolved in 6 or 8 c.c. of distilled water at room temperature, then it may be safely asserted that the xanthin is very greatly increased in quantity.

The stomach contents should be diluted with distilled water and boiled, and then filtered through filter-paper with the aid of a vacuum filter; the mass remaining on the filter should be again mixed with distilled water, boiled, and again filtered; this fluid is then treated in the same way as the urine.

117 Broadway.

MONSTERS.

By E. T. Milligan, M.D.,

Detroit, Mich.

On January 15, 1895, I was called, at 11.30 P.M., to attend Mrs. A——, who was in labor. On examination, the os was well dilated and the bag of waters presenting. I ruptured the bag of waters, and found the vertex presenting, the right occiput anterior, and could easily locate the anterior and posterior fontanelles. As the presentation was normal, the vagina short, well dilated and lubricated, and the labor pains strong and vigorous, I predicted a short labor. After waiting some time, I made another examination and found that, although the pains were strong and expulsive in character, the head was still in the same position. After waiting another hour, I found the head had descended a little, but there was no attempt whatever at flexion. One hour later I made another examination, and found the head had made another advance, but still flexion was absent. After another wait of an hour, I found the head had advanced on the perineum, but the descent was still unaccompanied with flexion. I passed my finger under the pubic arch, to ascertain, if possible, why flexion did not accompany descent, and discovered another child in the uterus, under the pubic arch, face presenting. As I never knew of two well-developed children presenting at the same time, and as a woman in labor does not care to be asked if twins or monstrosities are a peculiarity of her family, I had no example to guide me. When the next pain came on I placed the index-finger of my left hand on the brow of the baby under

the pubic arch; I pressed two fingers of my right hand well up in the rectum, and under the occiput of the baby first presenting, and during a pain, exerted pressure on the brow of the baby under the pubic arch, and with my finger on the rectum, flexed the head of the baby on the perineum. After flexion had taken place the head glided over the perineum and emerged from the vulva. After extraction of the head the shoulders did not follow. I passed my finger into the vagina and delivered the shoulders. After the shoulders were delivered, the remainder of the body refused to come. I passed my finger into the vagina, and found that another baby was attached to the one, "half out of the woods." I flexed the head and shoulders of the first baby against the pubic arch of the mother, and with my fingers again in the rectum, forced the second head along the perineum and through the vulva, the two bodies quickly following. As the monstrosity was dead I tied the cord at once. The abdomen of the mother did not diminish much in size, and fearing a fatal hemorrhage, I laid my two hands over the uterus and exerted gentle pressure. The uterus again contracted and expelled another child enclosed in an unruptured bag of amniotic fluid. I ruptured the bag, and tied the cord after it had ceased to pulsate. The last baby was alive and to-day is strong and vigorous. I seized the uterus at the fundus and expelled the placenta by the Credé method. I did not let go the uterus until I was positive it had well contracted and felt like a wooden ball. The monstrosities were well developed and joined together at the median line, at a point commencing at the junction of the manubrium with the gladiolus, terminating at the umbilicus, and laterally a line running from the axillary border of the scapula, extending to the tenth rib. There was but one placenta, which was quite large, and two cords, one of which supplied the monstrosities (as the accompanying photo shows), the

other cord supplied the last child. The monstrosities weighed 15½ pounds, and the last child weighed 7⅛ pounds, a combined weight of 22⅝ pounds. All the children were females. The mother was six hours in labor. There was no laceration whatever to the perineum. The parents were born in the United States, and deny any histories of monstrosities on either side. The mother has been pregnant on three different occasions, but gave birth to still-born babies between the sixth and seventh months. When she again became pregnant she came under my care with the hope that she would produce healthy offspring. I looked after her carefully, and as she was refined and educated, I had no trouble in having her obey my instructions. I gave her mercury in abundance, alternating with the iodide of potassium, combined with general tonics, properly cooked, plain food, and regulated exercise. At the sixth month of pregnancy I found traces of albumin in the urine, which disappeared on the administration of Epsom salts. At the seventh month she had to take to her bed, suffering from labor pains. I gave her a prescription containing fluid extract viburnum prunifolium, one ounce and a half; bromide of soda, two drachms; sulphate of morphine, one grain; water and sirup to make three ounces; one teaspoonful every two hours. On the next morning her pains had disappeared. I had her remain in bed one week, and continued the medicine, one teaspoonful thrice daily. The large size of the abdomen, at the seventh month, led her husband to believe she had arrived at full time. "My God! doctor," said he, "if my wife goes much longer she will be all belly." She had no further pain until her full time had elapsed, when she endeavored to supply her husband with as many live children as she had had dead ones.

66 La Brosse Street.

SEPTIC BULLETS AND SEPTIC POWDERS.[1]

By LOUIS A. LAGARDE,

CAPTAIN AND ASSISTANT SURGEON UNITED STATES ARMY.

Volume 56, No. 17, of the *New York Medical Journal*, October 22, 1892, contains a special report to the Surgeon-general, United States Army, entitled, "Can a Septic Bullet Infect a Gunshot Wound?" The evidence adduced in this report proves beyond doubt that projectiles, from hand weapons at least, are not purified by the act of firing, and that, when a specific virulent micro-organism like the bacillus anthracis is placed upon a projectile, and the latter is fired into a susceptible animal in such a manner as to wound him only, the animal will succumb to the corresponding infection, in the majority of cases. The experiments on animals, detailed in the special report to the Surgeon-General, were conducted at short range, never more than ten feet.

The question has often been asked whether it might be possible for bacteria to remain on a projectile during and after its transit at the actual ranges of, say three, five, six hundred yards or more. Without such experimental data the work detailed in the report quoted hitherto remains incomplete, and for this reason the following experiments were conducted at Fort Logan, Col., May 10, 1895:

Five sheep were shot at three and five hundred yards with the two hundred and thirty-grain steel-jacketed bullet of the thirty-calibre Krag-Jorgensen rifle. The projectile was propelled by thirty-seven grains of "Peyton" smokeless powder. Each projectile was infected a few moments before the firing took place with a recent virulent culture of the bacillus anthracis on an agar-agar slant. Four of the animals were wounded. One was killed outright; the bullet from the five hundred-yard stand passed through the large vessels of the neck and caused death by hemorrhage in a few minutes.

Of the wounded animals No. 1 received a wound, at five hundred yards, on the inside of the right ham near the shank. The projectile passed out, fracturing the ham bone. Death ensued sixty hours after the injury. Cover-slip preparations from the blood of the liver, spleen, and heart, stained with a watery solution of gentian violet, revealed the bacillus anthracis. Colonies of the bacillus anthracis were isolated on agar-agar plates inoculated from a bouillon suspension of the blood from each of the organs mentioned.

No. 4 was hit at three hundred yards in the left shoulder, the projectile making its exit on the right side of the neck. He never recovered from the effects of the injury sufficiently to enable him to regain his feet. He refused food and drink from the time he was shot until he died, on the fifth day. Cover-slips, prepared from the blood of the spleen, liver, and heart showed anthrax bacilli in nearly every field.

The other two animals, shot in the skin of the abdomen and in the right foreleg, respectively, at three hundred yards, recovered entirely.

These results show conclusively that the infection of anthrax can be carried on a projectile at long range, and that it is possible to thus infect susceptible animals.

Septic Powders.—*1. Black Powders.*—The extent of powder burn, tattoo, or marks inflicted at short range by firearms, etc., as observed in surgical practice, will convince anyone that the charge of powder is not entirely consumed in the generation of gases at the time of ignition. If one will recover the powder grains that can be caught in blotting-paper from firing revolvers at short range, and place these, together or singly, in a vessel, it will be found possible to ignite them almost invariably with a burning match, showing that the grains of powder that produce the tattoo of what we style "powder burn" are not destroyed by the act of firing.

It is estimated that only fifty-seven per cent. of the old black powder is consumed in generating the gases that cause the explosion, and that the remaining forty-three per cent. is thrown out in the original granular condition, each grain acting as a missile with velocity sufficient to inflict injury, the extent of which varies with the size of the powder grains, length of barrel, distance of the body from the muzzle, etc.

The bacteriology of gunpowders before and after firing, and the possibility of transmitting micro-organisms that may contaminate them into media or wounds at the moment of ignition is, I believe, a subject that has received no attention prior to the experiments about it to be enumerated.

The black gunpowder generally used in firearms is invariably contaminated with dirt, dust, and other impurities. This fact is so apparent that it hardly needs proof to demonstrate it. Still it was necessary for the purpose at hand to verify the matter, which I did, as follows:

Six gelatine rolls (Esmarch's plates) were prepared, each containing six grains by weight of Dupont's "F" black powder, such as our army has been in the habit of using for reloading the ammunition of the Springfield rifle and carbine.

Six bouillon tubes were similarly inoculated and placed in the incubator at 35° to 37° C. The latter were cloudy after the lapse of twenty-four hours, and hanging drops as well as cover-slips prepared from the different cultures contained bacteria of many different kinds. The gelatine rolls (Esmarch's plates) after forty-eight hours at the room temperature were invariably studded with colonies, varying in number and kind.

Sterilized black powder, when fired against plates of gelatine or agar-agar with blank cartridge or ball at short range from revolvers, rifles, or carbines, imparts

[1] Read before the Association of Military Surgeons of the United States, at Buffalo, N. Y., May 23, 1895.

no growth to the media in the majority of instances. When growth appears it is very sparing in the number of colonies. These may arise from the current of air that is forced against the plate with the expanding gases, or possibly from imperfect sterilization. The method of sterilizing adopted was to place the ammunition in an Arnold steam sterilizer for two hours. This does not always succeed, as some of the powder will show growth now and then when placed in suitable media.

As a matter of contrast to the negative results obtained by firing sterilized black powder into gelatine or agar-agar plates, if we take forty grains of black powder and mix it with ten grains of dust from the street, and fire the charge from a .45-calibre Springfield carbine at, say five feet, into gelatine or agar-agar plates, the plates will be found rich in colonies after the lapse of the prescribed time.

The experiments so far having justified the belief that unburnt grains of black powder might be made to carry micro-organisms into media, I determined to make the matter surer still by attempting to inoculate powder with a specific germ. I therefore inoculated black powder with anthrax spores as follows: The culture used was an old one on an agar-agar slant; the spores were mixed with fifty-five grains of powder taken from a shell of the .45 calibre Springfield carbine. The charge of powder was poured on a piece of white paper, and a platinum needle, properly sterilized in the flame, was passed once into the culture of anthrax spores, and then a number of times in and through the powder until the grains of the latter no longer adhered to the needle. The needle having been again sterilized, it was once more passed through the culture, thence through the powder as before. This was repeated four or five times for each charge of powder, six in all. The powder and ball were replaced in the shells. Two Petrie dishes, containing agar-agar, were placed in wire frames and the latter were suspended against the target four inches apart. The marksman, who held the muzzle of his carbine at five feet, was directed to locate the projectile as nearly as he could midway between the two plates. In this way a number of powder grains were collected on each of twelve plates, out of the six shots fired. The plates were at once placed in the incubator at 35° to 37° C. At the end of twenty-four hours four of them contained colonies of the bacillus anthracis.

Having recovered this uncommon germ in the manner stated, the proof seemed conclusive that contaminated black powder was apt to carry germs of any kind on those grains which had not ignited into media, and possibly into animals. To demonstrate the latter proposition I loaded six blank cartridges, each containing eighteen grains of black powder, infected in the manner described with anthrax spores. The weapon used was a .38-calibre Colt revolver, range one foot. Six rabbits were selected and each animal was shot in one or both ears. In four of the animals the unburnt grains of powder failed to penetrate the skin entirely—the grains projected above the surface; while in the other two the powder grains were for the most part well embedded in the skin and areolar tissue. The latter two animals sickened on the third day. One of them died on the fourth day, while the other recovered entirely. Cover-slips prepared from the blood of the heart, spleen, and liver of the dead animal, stained in a watery solution of methylene blue, revealed anthrax bacilli in nearly every field.

2. *Smokeless Powder.*—The experiments about to be described were conducted with the "Peyton" smokeless powder now used by the United States Army in the Krag-Jorgensen rifle. Although we have every reason to believe that this powder is contaminated by handling in the same way that the old black powder is, yet we fail to obtain growth when we place a few grains of it in media like bouillon, gelatine, or agar-agar, etc. This powder imparts a yellowish color to the media. After repeated trials I have failed in cultivating prodigiosus in bouillon to which a few grains of the powder had been added. It would seem from this that the "Peyton" powder contains a substance which inhibits the growth of certain bacteria in the medium mentioned. On the other hand, if a bouillon tube containing a few grains of the "Peyton" powder is inoculated with anthrax spores, growth will be noticed at the end of twenty-four hours under favorable conditions of temperature, showing that the restraining influence of the powder does not apply to the more resistant forms of germ life.

If the experiment of firing black powder into agar-agar or gelatine plates be repeated with the "Peyton" powder, whether this be sterilized or not, the powder grains which are caught on the medium impart no growth, as a rule. The yellowish discoloration already mentioned is invariably noticed around each grain. If, however, we purposely mix earth in the proportion of ten to twenty per cent. with the powder before firing, colonies will appear in great numbers in the medium beyond the areas of discoloration, and sparingly, if at all, within the latter.

Out of six gelatine plates fired into at ten feet with the "Peyton" powder which was previously contaminated with anthrax spores, colonies of the bacillus anthracis were observed in two of the plates.

Of three rabbits shot in the ears at four feet by the Krag-Jorgensen rifle loaded with thirty-seven grains (blank cartridge) of the "Peyton" powder which had previously been contaminated with anthrax spores in the manner already mentioned with black powder, one of the animals sickened on the third day and died on the fifth day. Cover-slips properly prepared from the blood of the spleen, liver, and heart, and stained with a watery solution of gentian-violet, revealed the presence of anthrax bacilli, though few in number. Sections of the liver and spleen, stained by Gram's method, exhibited the presence of the same bacilli in the vessels.

Conclusions.—The experiments and their positive results, as enumerated in this paper, as well as those detailed in a paper read before the Pan-American Congress, and also in the paper already mentioned in the *New York Medical Journal* of October 22, 1892, offer, in my opinion, a reasonable explanation for the occurrence of various infections like tetanus, malignant œdema, erysipelas, etc., in a fair proportion of the cases following gunshot injuries.

H. Nimier, a French army surgeon, in the *Archives de Médecine et de Pharmacie Militaires*, No. 25, 1894, relates four cases of tetanus after powder burn from blank cartridges. The injuries were inflicted during sham battles. The relief corps were promptly on the ground, and although all antiseptic precautions were observed, infection took place. In a recent letter Dr. Nimier informs me that the powder which caused the injuries was the old black powder.

Cases like these are difficult to comprehend unless we assume that the gunpowder was infected, or that, as often happens, tetanus earth had become accidentally lodged in the muzzle of the guns.

I believe that my experiments and their results justify the opinion that the infection of tetanus and malignant œdema can be conveyed by one or both of the ways mentioned, and unless I should be forestalled in the attempt, I hope to be able to demonstrate this as a fact to the Association at no distant day.

The Average Daily Amount of Opium used in India.—Sir William Roberts cites some illustrations of the large quantities of opium occasionally consumed by opium-eaters in India. He says that the average tolerance of the natives, judging from the practice of opium-eaters, appears to range from four to twelve grains of opium per day.

REPAIR AFTER A BONE-FLAP OPERATION ON THE SKULL.[1]

By GEORGE WOOLSEY, M.D.,

NEW YORK,

SURGEON TO BELLEVUE HOSPITAL; PROFESSOR OF ANATOMY AND CLINICAL SURGERY IN THE MEDICAL DEPARTMENT, UNIVERSITY OF THE CITY OF NEW YORK.

Some points as to the operation and the repair of the operation wound in the following case seem to be of sufficient interest to justify reporting it. The case was similar clinically to those cases described by Dr. Starr in his work on "Brain Surgery"[2] as presenting imbecility with hemiplegia.. The pathological condition found at the autopsy, a year and a half after the operation, was porencephalus with localized atrophy or agenesis. The history of the case is briefly as follows:

D. O. C——, aged fourteen, was considered a healthy infant. He had spells of indigestion and while teething one or two convulsions. At five years of age, after slight exposure to the July sun, he had seven convulsions of the entire right side lasting seventeen hours. Twitchings were continuous for the first five hours and interrupted for the succeeding twelve hours. When consciousness returned there was paralysis and deafness on the right side and loss of speech. He remained in this condition for five weeks, when he began to move the right foot, and in ten weeks he walked with a cane. Hearing returned slowly on the affected side and it was six months after the attack before he began to speak, and speech has ever since been imperfect. His memory was good. One year after the attack he could walk well, but had little use of the right hand. At this time he had one or two epileptiform convulsions a day, which became more frequent and severe after an attack of measles at eleven years of age. He now began to fall in the seizures, which gradually increased in number and severity during the last five years. Among others Drs. Janeway, Weir Mitchell, and E. D. Fisher had been consulted, by the latter of whom he was referred to me with a view to operation, as a last resort, all other means having failed.

On admission to Bellevue Hospital, February 14, 1893, although generally well developed and well nourished, his right upper extremity showed contractures, atrophied muscles, and poor circulation, causing a cold surface and bluish skin. Speech was a decided effort, sometimes causing congestion of the face, and the result was imperfect. On attempting speech the motions of the lips and tongue were exaggerated and his chin was often wet with the increased salivary secretion. He was quite religious, the religious side of his mind being more developed than the intellectual.

After admission he had three or four epileptiform convulsions during twenty-four hours, sometimes with general twitching, sometimes with twitching of the left side only. His head was shaved and a soft-soap poultice and then an antiseptic compress applied to prepare for the operation on February 16, 1893. No abnormal appearance of the head was noticed. A horseshoe-shaped incision was made over the lower two-thirds or three-fourths of the left sulcus of Rolando, the base of the incision being directed downward toward the blood-supply. To prevent free bleeding and consequent increase of shock the incision was first outlined by a row of temporary, interrupted, overlapping silk sutures one-half inch beyond it. Similar sutures may be applied across the base of the flap in any given case if required. After retraction of the scalp the incision was carried down through the periosteum, which was stripped back for half an inch throughout the incision. The bone thus exposed was chiselled through by means of two V-shaped wood-carver's chisels of larger and smaller angles, the chisel with the larger angle being used first, that with the smaller angle last to complete the bottom of the groove. These chisels were bevelled and sharpened at the expense of the inner surface, for when sharpened as is usually done they have to be held so vertically that a large part of the blow of the mallet goes to produce concussion of the brain, as I had found in a previous case.

One remarkable feature of the case was the thickness of the skull, consisting mostly of diploëic substance, measuring three-fourths to one inch, and increasing the mechanical difficulty of the operation. Notwithstanding this, the division of the bone, was accomplished without great delay, and after partially chiselling through the base of the flap from either side, the flap of scalp, pericranium and bone, was turned down, exposing an area of dura mater measuring about two by two and three-fourths inches. The dura, which appeared normal though bulging, was divided in a semicircle, about one-third of an inch from the bony margin, and reflected back, exposing the pia mater. This appeared normal, but the brain bulged abnormally, showed but little pulsation, and on palpation felt unusually tense and elastic.

A small aseptic aspirating needle was introduced about three-fourths to one inch in the direction of the lateral ventricles from the posterior part of the exposed area, and a clear, pale, straw-colored fluid flowed out, confirming the diagnosis of porencephalus. About an ounce and a half of this fluid was kept for examination, and as much as one ounce more flowed away. The chemical examination of the fluid showed a very low percentage (less than 1.5 per cent.) of albumin, indicating that it was cerebro-spinal fluid from an enlarged lateral ventricle rather than fluid from an independent cyst.

A bundle of a few strands of silkworm-gut was passed alongside the needle into the cystic cavity for drainage and brought out of the postero-inferior part of the wound. Suture of dura mater, pericranium, and scalp with catgut in three layers. The operation was fairly well borne. He was very restless and nauseated with occasional vomiting for the next three days, which may have been due to slight concussion or to cerebral irritation from the wound. During the first twenty-four hours he had three convulsions, two during the second, and none during the third, twitching of the left side being still pronounced during the convulsions. The temperature rose to 103° F. on the second day, and again to 104° F. on the fourth, but otherwise was not much elevated.

The wound was dressed on the second, third, and fourth days, and afterward only occasionally. It healed by first intention. On the third day the drainage, which had been quite free at first, was discontinued on the advice of Dr. Fisher. Although about this time his mental and physical condition seemed as good or better than before operation, yet he soon sank into a semi-comatose state following a period of religious excitement. He passed urine and fæces in bed, scarcely spoke, and was very helpless.

From this condition he slowly improved, and when he left the hospital a month or so later he was in about the same condition as on entering. After returning home his family thought him better than before for a time. He lived for a year and eight months or so, gradually becoming worse toward the end, and died October 14, 1894.

Dr. E. D. Fisher was given the opportunity of examining the skull and brain, and found the following condition: The skull was found enormously thickened, especially on the left side, where it measured one inch in thickness, but also extending somewhat onto the right side in front. The "bone-flap," raised and replaced at the operation, was solidly united to the surrounding bone by a smooth, even, and non-adherent line of union. The incision in the dura mater was beautifully healed, and could only be located by a

[1] Read before the Section on General Surgery of the New York Academy of Medicine, May 13, 1895.

[2] Chapter III., Class 1.

slightly opaque line, seen on holding it up to the light. There were no adhesions between the membranes or between the dura and the bone. On the left side "there was a cavity extending from the motor area of the cortex into and continuous with the lateral ventricles. The whole left hemisphere was atrophied, the convolutions being shrivelled in appearance and the volume one-third less than the opposite hemisphere. There was evidence of a descending degeneration through the pyramidal tract as shown by the decreased size of the pons on the same side as the lesion, and of the opposite lateral tract of the spinal cord below the medulla. The opposite hemisphere of the cerebellum was also much smaller than its fellow. The pathological changes pointed either to a congenital condition, or at least one occurring in early childhood. I consider the lesion to have been a thrombosis or embolism in the course of the middle cerebral artery, leading to softening and final absorption of the brain substance, resulting in a cyst opening into the ventricles." [1]

At the time he left the hospital a simple trephining with long-continued drainage was advised, but not accepted. Kocher's encouraging results with long-continued drainage in cases of cerebral cysts are well known and promise more than any other plan of treatment. Whether this case would have been benefited by such treatment, it is impossible to say; but, judging from the pathological condition found post mortem, and from an unsuccessful experience in a somewhat similar condition subsequently, it seems to me extremely doubtful.

Several surgical points seem to be worthy of emphasis: 1. The considerable area of brain surface exposed. This in a case previously operated enabled me to discover and remove a spicule of bone piercing the dura mater and embedded in a small cortical cyst, which had escaped detection in a previous trephining.

2. The chisels used should be so bevelled on their inner surfaces that they may be held as flat as possible, so that as little as may be of the blow of the mallet will act directly to cause concussion, and as much as possible will glance from the surface, at the same time that it effects the cutting of the bone. This point was well exemplified in the first two cases that I operated upon by the flap method. In the first case chisels were used bevelled on their outer surface, and very marked concussion resulted. In the second case, the one above reported, in spite of the thickness of the skull, there was comparatively little concussion.

3. Hemorrhage can be spared and shock much diminished by encircling the proposed line of incision at a little distance by a number of temporary overlapping sutures. In the last case that I operated upon I did not employ this plan until forced to do so by the free bleeding, and the blood lost in the meantime added much to the subsequent shock.

4. This case shows (*a*) that this method is applicable even in the most unfavorable cases where the skull is enormously thickened. (*b*) That the bone-flap may heal firmly and with a smooth inner surface not adherent to parts beneath. From a clinical stand-point the replacing and reuniting of bone, thus protecting the brain substance, is very desirable, especially in cases where a large area is exposed. (*c*) That dura mater, after incision and suture and the use of drainage of the lateral ventricles, passing through the suture, for two or three days, may heal without adhesion either to the bone or to the pia mater. This seems to me to be an important and encouraging fact in exploratory or other operations upon the brain, as it is not what has been usually expected under the circumstances. After a trephining, when the button of bone is not replaced, we invariably expect to have the dura mater become adherent to the scalp. The contraction of this new-formed cicatricial tissue may reproduce the irritation temporarily removed by the operation. In fact, the great obstacle of cerebral surgery lies in the fact that the removal of a scar or any incision of the parts necessitates a scar in the healing process following the operation, and this notwithstanding many ingenious devices to prevent it.

For a time surgeons were very sanguine and enthusiastic in brain surgery and remarkable developments were made, but a reaction set in when it was found that many of the cases of supposed cures, already in the minority, relapsed after a certain length of time.

In view of these facts it seems encouraging to find a case where a large area was exposed for exploration, where the dura was incised, and the lateral ventricles drained for a few days, and yet a year and eight months after the operation there was perfect and smooth union and no adhesions.

Whether such a result is to be expected from similar operations, or was exceptional in this case, cannot be judged from a single instance, but only after further experience. If this result should be confirmed by other cases the outlook for operations on the coverings, if not on the cortex of the brain, would be more encouraging.

117 East Thirty-sixth Street.

[1] Report of Dr. E. D. Fisher.

Progress of Medical Science.

A New Method of Cholecystotomy.—Block (*Rev. de Chir.*, February, *British Medical Journal*, March, 1895) describes a new method of performing cholecystotomy, devised with the view of avoiding on the one hand peritonitis, which often results from the giving way of sutures after immediate closure of the wound in the gall-bladder, and, on the other hand, the formation of firm adhesions between the gall-bladder and the abdominal wall after the establishment of a temporary fistula. In the method called extra-abdominal cholecystotomy, which is advocated by the author, and was successfully practised by him in a case recorded in his paper, the distended gall-bladder is drawn through the abdominal wound, and a portion about the size of a hen's egg outside this wound by sutures, until adhesions have formed and the peritoneal cavity has been closed. The gall-bladder is then opened, and any gall-stones it may contain are removed. The wound in its coats having been closed by sutures, the gall-bladder, after a further interval to allow of complete cicatrization, is separated from the margins of the incision in the abdominal wall and returned into the peritoneal cavity, the external wound being finally closed.

The Treatment of Chlorotic Dyspepsia.—Dr. Huchard directs that milk shall be used, or, if this is badly borne, pure water or a hot, weak, infusion of tea (hot drinks excite the gastric secretion), eggs, *purée* of vegetables, lean fish, fowl, and cooked fruits. One-half hour before the meal a small dose of an alkali, as sodium bicarbonate, seven grains, should be prescribed, for the purpose of exciting the flow of gastric juice. At the same interval after it a Madeira glass of hydrochloric acid in solution in water, one to two hundred and fifty. The hydrochloric may be replaced by lactic acid, fifteen to thirty grains, after meals. It is necessary to forbid the use of wines, quinquina wine, strong beers, alcoholic drinks, and stimulating food. If there are gaseous formations, lavage, either of pure water or water containing salicylic acid, one per mille, is indicated. After two to four weeks of this treatment the use of the preparations of iron can be begun, of which the proto-salts are preferable, oxalate, lactate, chloride, and iodide, in small doses, one and one-half grain, twice daily, and not to exceed six and one-half grains daily, if we shall avoid symptoms of gastric intolerance.—*The American Journal of the Medical Sciences.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 43, 45, & 47 East Tenth Street.

New York, June 22, 1895.

A LANDMARK IN PUBLIC HYGIENE.

MODERN statecraft has wisely taken upon itself the function of protecting nations and communities against the invasion of disease. Driven by the sadly repeated experiences of less enlightened people to the realization that disease and death result in far greater loss to the community than wars or financial convulsions, the public men of more advanced nations have sought to protect their people against epidemics, which have, until recent time, brought fatal stagnation upon commerce and clogged the wheels of prosperity. Quarantine regulations and other sanitary requirements have thus come to be enforced by legal enactment. Evolved from these, laws against adulteration of food and drink, laws to regulate the standard of illuminating fluids, and others seeking to protect the individual, were entered upon the statute-books. Laws to provide for proper construction, plumbing, light, and ventilation in tenement-houses, and to prevent overcrowding of the dependent classes, are the most recent outcome of that higher phase of public hygiene which recognizes the full force of the fact that public health is more endangered by disregard of the sanitary conditions of the poor than by all other causes. This class forms a large proportion of all communities; their crowded condition and unclean habits, enforced or voluntary, favor the more rapid introduction and spread of contagious and infectious diseases, which may thus be readily introduced among other classes of the population. To enable the dependent portion of a community to withstand the inroads of disease is to erect a bulwark for the whole population. The Legislature of New York has demonstrated its recognition of this truth by the passage of two acts, which distinguish it as one of the most enlightened legislative bodies of the day. One is an act creating two public parks in the very midst of the overcrowded tenement district, and appropriating three million dollars for the purpose. The benefits that will accrue to these people by reason of the increased breathing-space thus placed at their disposal is incalculable, and readily appreciated by the most superficial observer. But a far more potent auxiliary for the maintenance of health and resistance to disease is afforded by another act of the Legislature, which provides that all cities of the first and second classes shall establish and maintain such number of free public baths as the local board of health may determine to be necessary, to be kept open every day for fourteen hours, provided with hot and cold water, etc. Thus it has been made incumbent upon the authorities of all large cities in this State to furnish the means of personal cleanliness to its people by baths which shall be as free and accessible to them as the air they breathe.

The enactment of these laws may be regarded as a landmark in public hygiene. The first furnishes pure air to aid the system in ridding itself of products which are eliminated by the lungs; the other furnishes means for furthering the elimination of impurities through the skin. While the importance of the former is accepted, the full import of the latter still requires to be enforced upon the lay public. Upon the medical profession devolves the duty of inculcating the enormous value of personal cleanliness as a means of preserving the body in health and endowing it with resistance to disease. It behooves us to encourage, support, and urge upon the authorities the immediate execution of the salutary laws providing free baths for the dependent classes.

This city is especially fortunate in the possession of a Board of Health which has signalized its justly high position among sanitary bodies by excellent scientific and practical work. We are informed that the City Board of Health has long been interested in the public bath question, and has encouraged the originator of the free bath movement in his earlier struggles for the passage of the recent laws. It is gratifying, therefore, to note that the Board is also earnestly considering the best method of carrying the public bath act into vigorous execution by recommending the construction of several rain baths. The adoption of the rain bath has solved the public bath problem satisfactorily. By its means alone large masses of people may receive thorough cleansing without the possibility of contamination, and with the most economical expenditure of money on the part of the city and the least loss of time on the part of the bather. Its superiority to the swimming pool is unquestioned. It was introduced in this country by Dr. Simon Baruch in his report as chairman of the Committee of Hygiene and Public Health of the County Medical Society, in October, 1889, and has since that time been adopted by many public institutions and philanthropic societies. That it is popular among the working classes is demonstrated by the fact that the People's Bath at Centre Market Place, in this city, has bathed over eighty thousand people in one year, despite the fact that a fee of five cents was exacted. Indeed, this enterprise, which was the immediate offspring of Dr. Baruch's report to the County Society, has demonstrated forcibly the superiority of the rain bath as a public bath, inasmuch as in a space of sixty-one feet by twenty-seven feet it furnishes accommodations for nine hundred bathers daily. There is no reason to doubt that our city authorities will adopt this style of bath.

It has been suggested that a portion of the new parks and several of the older ones in the tenement district be utilized for the erection of public baths. The space occupied would be exceedingly small; the buildings require only one story, and would therefore not interfere in the slightest degree with the chief object of the park, which is to furnish breathing space for the tenement dwellers. The adoption of this course

would not only save the cost of building lots, but it would enhance the value of one hygienic measure by the utilization of the other. The Park Board will doubtless realize the importance of this combination of recreation with utility, and lay no obstacles in the way of accomplishing so salutary a movement without marring the comfort and pleasure of the populace.

We would urge the rapid construction of these public baths upon our city authorities, who may thus not only endear themselves to the hearts of a grateful constituency, but also erect for themselves a monument more enduring than brass.

THE SCHOOL TEMPERANCE LAW.

Governor Morton has signed the new temperance school law providing for the regular and systematic instruction of children in the nature of alcoholic drinks and other narcotics. Viewed from one aspect, we are not surprised to learn that the said law was unanimously passed by the late Legislature, and that the Governor himself had no hesitation in affixing his judicial sanction to the measure. In the line of public policy the movement naturally appears to be based on the soundest of principles. The evils of intemperance in stimulants and narcotics are manifold and terrible, and any education, elementary or otherwise, that may tend to mitigate them needs every encouragement.

The question whether or not this particular method will be practically beneficial, remains to be seen. On its face it does not appear to be necessary to educate children concerning any principles of belief or action that they cannot directly or indirectly apply to their own and immediate needs. Why they should be guarded against these forms of intemperance any more than any other possible evil, is not easily seen. Aside from an extra burden in their studies, it is impossible to teach them properly on the real points at issue. It may be enough to say that liquor and opiates are poisons, and should be avoided as such, but to attempt to explain, through necessarily incompetent teachers, the whys and wherefores of pathological changes of tissues, the relation of cause and effect in functional and organic disturbances of the kidney, stomach, brain, and nervous system generally, is absurdly inconsistent with the ostensible aim in view.

The law is a most unwise and oppressive one, and is only to be looked upon as an example of the morbid excesses of the temperate.

STATE CARE BILL NOT APPROVED.

Mayor Strong refused to approve of the bill for transferring the care of the city insane to the care of the State, and Governor Morton has also declined to sign the bill, despite the pressure brought to bear upon him from all sides. The State Lunacy Commission worked itself into a very hysterical condition over the matter, and the Chairman of the Commission wrote a letter to the Governor, which was of course published in all the daily papers, and which portrayed the prospective condition of the city insane in New York in the most affecting way.

Now that the matter has been settled for the present, we trust that the public, or, more particularly the State Lunacy Commission and those who have made a personal matter of the State Care Bill, will allow the authorities of this city to have their chance. The city at present has an excellent Board of Charity Commissioners, who are ambitious to place the care of the city insane, as well as of the other sick, upon the very best basis. They will have, we believe, the hearty co-operation of the medical profession of the city, and we trust that the philanthropists who have felt that New York could not possibly care for its own sick will at least give the present authorities an opportunity to try. In some curious way it happened, during the last few months, that absolutely nothing was introduced into the daily papers, except articles laudatory of the State Lunacy Commission and of the bill for the State care of the insane. No other side of the subject was allowed to appear, yet we venture to say that there is another side, and we have at various times tried to present it calmly and honestly. We trust that this side will be considered now.

THE HARLEM HOSPITAL.

Some surprise was created in medical circles last week by the announcement that the Medical Board of the Harlem Hospital had been removed. Explanations from the Charity Commissioners showed, however, that this was simply a part of a scheme for the reorganization of the service, and did not reflect at all on the medical men who composed the board. It is, so far as we can learn, the design of the Commissioners of Charities and Correction to place the nominating power for positions on this board in the hands of the three undergraduate medical colleges of the city and the non-collegiate division of Bellevue Hospital. The Commissioners in this way expect to throw the responsibility of securing good men for the position upon the teaching organizations of the city. This plan has worked very well in connection with Bellevue Hospital, and it is, we presume, inferred that it will be equally successful if applied to other institutions under their care.

The Medico-Legal Society of Chicago.—The following officers have been elected for the current year: *President*, Edmund J. Doering, M.D.; *Vice-Presidents*, Cassius D. Westcott, M.D., and Sanger Brown, M.D.; *Treasurer*, Joseph Matteson, M.D.; *Secretary*, John Ridlon, M.D.

Commencement of the College of Physicians and Surgeons.— The medical department of Columbia University held its annual Commencement in connection with that of the University on June 13th.

St. Luke's Hospital, expects to move its patients to its new building in the fall. As a result of this proposed change, and the sale of a good many lots on its present property, it has been obliged to decline to receive new patients for the present.

News of the Week.

The Cartwright Prize, offered by the Alumni Association of the College of Physicians and Surgeons, was awarded to Dr. James Ewing.

Laboratory Infection and Accident Insurance.—A curious case has occurred in Hamburg. Dr. Oergel, of the Hamburg Bacteriological Institute, died recently of an attack of cholera contracted while working in the laboratory with cholera bacilli. He was insured against death from accident, but not against death from disease. His widow brought suit for the insurance money, claiming that the death under the circumstances was really accidental, and not, strictly speaking, death from an infectious disease. The widow, as might have been expected, lost the case.

The Confinement of Mr. Andrew Lang.—Mr. Andrew Lang, who among his other duties has assumed that of correcting all the minor mistakes of the world, has recently criticised Mr. Brander Matthews for asserting that certain alleged Americanisms were really Britishisms. Mr. Lang denies in part, explains in part, and ends with a freshly gathered Americanism from the New York *Herald*, which he considers to be a particularly aberrant form of speech, viz.: "Mrs. —— has been successfully confined." The *British Medical Journal* prints a letter from a correspondent who in a very liberal spirit denies that the expression is incorrect, and says that if the Americans devised this phrase they deserve credit for their invention.

Utah State Medical Society.—In February of the present year a Medical Society was organized in Utah, its membership comprising almost all of the best known physicians in the Territory. The first annual meeting will be held October 1st and 2d. The following is a list of officers elected for the first year: *President*, F. S. Bascom, M.D.; *First Vice-President*, Walter R. Pike, M.D.; *Second Vice-President*, G. W. Perkins, M.D.; *Secretary*, J. N. Harrison, M.D.; *Treasurer*, S. M. Wilson, M.D.

Alumni Association College of Physicians and Surgeons.—The following change in the constitution of the Alumni Association was made at the annual meeting held June 10, 1895. All graduates of the College of Physicians and Surgeons in good standing in the profession, or engaged in other honorable occupations, may become members of this Association upon notifying the secretary of such desire and upon the payment of annual dues of $3.

The Thanatopsis Home.—*The Journal of the American Medical Association* refers to the fact that the *Evening Post* has urged the advantages of a "Home for the Dying" in this city. It is suggested that it be called the Thanatopsis Home, as being more appropriate than Home for the Dying, and as doing honor to the former great editor of the *Post*.

The Johns Hopkins Hospital is to build an addition to its dispensary.

Professor Von Esmarch has been made an honorary member of the Académie de Médecine.

The Late Dr. Matthew D. Field.—The following was passed at a recent meeting of the Alumni Association of Bellevue Hospital:

Whereas, Death has removed from our midst our fellow-member, Dr. Matthew D. Field,

Resolved, That the Society of Alumni of Bellevue Hospital has lost a valued and representative member whose devotion and interest did much to advance the Society;

Resolved, That we extend to his family our sincere sympathy in their great loss;

Resolved, That a copy of these resolutions be entered on the minutes of the Society, and that they be published in the New York medical journals.

Wisner R. Townsend, *Chairman*,
William B. Anderton,
Gorham Bacon.

Dr. J. R. Quinn, of Brooklyn, has recovered $8,000 for an injury caused by a brewer's truck colliding with the doctor's gig and throwing him onto the pavement.

A School of Medicine for Women is to be opened at St. Petersburg, Russia, under the auspices of the State.

Medical Missions in India.—This is the title of a small quarterly journal published at Ajmere. The subscriptions for the journal are taken by Dr. Carleton, of Philadelphia, and the price is the modest one of forty cents per annum.

A Curious Law of the State of Oregon.—A clause in the laws of Oregon provides that every physician who shall use or prescribe any opium, morphine, or other narcotic, shall enter in a book kept for such purpose a full record thereof, and this record must be open for the inspection of the public. It is also provided that any physician who shall use or prescribe any narcotic shall first procure from the County Court a license to dispense the same. The law is several years old, and is naturally a dead letter.

Uniforms of Army Surgeons.—During the war the army surgeons wore for a short time a green sash as an emblem of their calling. This was soon changed for the letters "M.D.," which were inscribed upon the shoulder of the coat. Later on a shield was worn as being less of an advertisement of the occupation of a surgeon. It is proposed to change the insignia of the medical corps again, and the proposal is made that the Geneva cross be adopted, this symbol to be worn upon the cap and the shoulders of the coat.

Meetings of Societies.—The Ninth French Surgical Congress will be held in Paris during the week beginning October 21st. The two subjects for the set discussions are: 1, Surgery of the Lungs, not Including the Pleura; and 2, Early or Late Operative Interference in Fractures of the Bones, those of the Cranium and Spinal Column Excepted. The President of the Congress will be M. Eugène Bœckel, and the Secretary M. Lucien Picqué, 8 rue d'Isly, Paris.—The French Congress of Mental and Nervous Diseases will hold its annual meeting at Bordeaux on August 1st.—The Association of German Alienists will hold its annual meeting this year in Hamburg, on September 13th and 14th.

Obituary Notes.—Dr. Alexander Pope died suddenly, at his residence in this city, on June 12th. Dr. Pope was found dead in his bed at midnight, his death being due, it is supposed, to heart failure. He was thirty-five years of age, a graduate of the University of Athens and the College of Physicians and Surgeons of New York. He had been connected for a time with the Polyclinic and the Vanderbilt Clinic of this city.—Dr. W. Carroll Chapman, a prominent physician of Louisville, Ky., died in that city, on May 28th, of cerebro-spinal fever.—Dr. William B. Wallace and his son, Dr. Alphonse Wallace, of this city, both died of pneumonia on June 7th. The elder Dr. Wallace graduated from the College of Physicans and Surgeons in 1871, and subsequently built up a large practice. He was known to the public as an ardent Irish patriot, and was considered one of the most eloquent orators among his countrymen in America. He was one of the organizers of the Irish National Land League of America. Dr. Alphonse Wallace was twenty-seven years of age at the time of his death, and was well known among the medical fraternity as the examining physician of the Department of Charities and Correction.—Dr. Aristide Verneuil, the well-known French surgeon, died in Paris, on June 14th, at the age of seventy-two.

Smuggling Phenacetin.—It is stated that phenacetin and sulphonal in large quantities have been smuggled into the United States by way of Canada.

Disciplinary Treatment for Degeneracy.—We are pleased to learn from our esteemed contemporary the *British Medical Journal*, that the health of Mr. Oscar Wilde, now in penitential seclusion, is very good.

Dr. Oscar H. Allis has been awarded the S. D. Gross Prize of $1,000 for an essay entitled "An Inquiry into the Difficulties Encountered in the Reduction of Dislocation of the Hip."

Heroism of Medical Officers in the Chinese War.—An item which must excite admiration is reported by a correspondent at Wei-hai-wei in the current number of the *Broad Arrow*: "Now came a touching proof of heroic devotion to duty. While the storm of lead was still hurtling thickly through the air, a company of Red Cross men, always well to the front, appeared on the field, stolidly marching out from the ravines, two and two, with stretchers and 'first-aid' appliances for their comrades, right under the withering fire from the gunboat, with never a moment's hesitation. Unarmed, but for a paltry dirk at the side, helpless in any case against such an attack, with foes heedless or ignorant of the sacred significance of the Red Cross badge, they did not flinch for a moment on their errand of mercy. It would have been easy to wait until the fire should cease, but they nobly went on and did their work as if on their parade-ground at home. One by one the dead and wounded were sought out all over that wide field of blood, and borne away, until within twenty minutes the place was completely cleared of every man, living or dead. Colonel Taylor, A.M.S., declared it the most splendid deed he ever saw, and the other foreign attachés who saw it were equally emphatic in their praise."

A Heavy Brain.—Dr. James Middlemass, of Edinburgh, reports the case of a senile dement who died at the age of seventy of an attack of pneumonia. The brain weighed immediately after removal 65¼ ounces. The man had been insane for many years, also deaf, dumb, and nearly blind. The interest in the case lies in the fact that he had a brain of maximum weight which was practically of no use to him at all, for he had been demented for many years. Dr. Levinge has reported the case of an imbecile who had a brain weighing 70½ ounces.

Increase of the Medical Profession.—Professor Brouardel, at a recent meeting of the Medical Association of the Department of the Seine, said that the increase in the number of medical students in France continued to be very great. In all the French faculties the number of physicians, he said, were twice as numerous as they were ten years ago. The cause of this, Professor Brouardel thinks, is the publicity accorded to the achievements of medical science. Day by day, he says, one sees in the newspapers the great importance attached to public health, and parents conclude that medicine offers a great and lucrative career for their sons. The medical profession of France is already overcrowded and, promises to suffer very much more from this state.

Mandelate of Antipyrin.—M. Rehn states that this salt possesses the properties of the ordinary form of antipyrin without being poisonous. It is obtained by treating antipyrin with mandelic acid. The dose given is five to ten centigrammes for children from three to five years of age.

Dr. Heitzmann, of this city, has been visiting Vienna, and was recently a guest of the Vienna Medical Society. He there read a paper on his microscopical researches, in which he asserted that he was the first to prove that the red blood-cells had a reticulated structure.

Abuse of Lunatics by Monks.—Brother Heinrich, one of the monks at Mariaberg, Prussia, has been arrested on the charge of ill-treating the insane patients in the monastery. The exposure of the cruel treatment of the insane has led to a demand in the Prussian Landtag, that the Government take effective measures to render such misdeeds impossible in the future, and to regulate the conduct of that and similar asylums in accordance with medical science and under complete State surveillance.

New York Polyclinic.—At the last meeting of the Faculty of the Polyclinic Medical School and Hospital, Dr. Wilbur B. Marple was elected Professor of Ophthalmology; Dr. W. R. Pryor, Professor of Gynecology; and Dr. W. R. Townsend, Professor of Orthopædic Surgery.

Yale Medical School.—The annual address in medicine will be delivered by Dr. T. Mitchell Prudden, of New York City, at the Battell Chapel, Yale University, on Tuesday, June 25th, at 12 o'clock, noon. The subject is "New Outlooks in the Science and Art and Medicine." A reception will be given to the orator in the evening at the residence of Professor W. H. Carmalt.

Society Reports.

AMERICAN GYNECOLOGICAL SOCIETY.

Twentieth Annual Meeting, held in Baltimore, May 28, 29, and 30, 1895.

MATTHEW D. MANN, M.D., OF BUFFALO, PRESIDENT.

(Continued from page 761.)

THIRD DAY, THURSDAY, MAY 30TH.

Specimens Removed by Vaginal and Abdominal Hysterectomy.—DR. R. STANSBURY SUTTON, of Pittsburg, presented a number of smaller uterine fibroids removed with the uterus per vaginam, and some much larger, removed by suprapubic hysterectomy, the entire number of cases so operated upon from November 1, 1894, to May 1, 1895, having been twelve, with twelve recoveries. In one of the cases the appendages had been removed twenty months previously, but the woman had not been cured, and he might say that in this and several of the other cases the only procedure which offered a cure was total castration. Dr. Sutton had removed the uterus with fibroid and fœtus in three cases, all of the women recovering. He was always willing to sacrifice the life of the fœtus in order to save that of the mother.

The discussion on the papers of Drs. Jacobs, Wathen, Henrotin, and Sutton was then opened by DR. MONTGOMERY, of Philadelphia, who thought that no other papers would have a greater influence on the profession and upon the welfare of those coming under their care. He was sure that all would consider the questions raised without prejudice and solely from the stand-point of obtaining the best results, remote as well as immediate, for their patients. After reviewing the figures given in Dr. Jacobs's paper, Dr. Montgomery stated that no other operative procedure than total vaginal castration could have given better immediate results for the class of cases under consideration. A total mortality of only three per cent. in a large series of cases naturally raised the question whether vaginal hysterectomy should not be preferred to the abdominal method. Dr. Montgomery seemed to think that the complication of fistulæ, which occurred only nine times in Dr. Jacobs's series of four hundred and three cases of total vaginal castration, was more than offset by the occurrence of the same accident, of inflammations arising from the presence of ligatures, etc., in the abdominal operation. Then the latter method had the further disadvantage of a longer convalescence, an abdominal scar, danger of subsequent hernia. The vaginal method had the advantage that the first step could be used as an exploratory one to determine whether it was necessary to go further.

Dr. Montgomery would not go as far as Dr. Jacobs, and assert that in every case of bilateral disease of the appendages the ovaries, tubes, and uterus should be removed. Nor would he be willing to admit that in every case of ectopic gestation both tubes and ovaries were involved. Indeed, he had seen, as he supposed many others had, cases in which pregnancy had occurred after removal of one tube and ovary for ectopic pregnancy. He did not, therefore, regard this as an indication for hysterectomy, and he was inclined to think that the site of the disease could best be reached through the abdominal route.

Dr. Montgomery approved of the vaginal method in removing the uterus for malignant disease and fibroids, but in the case of the latter he agreed with those who held that in some instances the tumor could be taken out and the uterus left. The speaker also thought that in some cases of pelvic exudation, and even of abscess of one ovary, an operation short of castration could be performed which would restore the patient's health and leave her in condition to bear progeny.

DR. J. M. BALDY, of Philadelphia, said he would limit his remarks to a comparison of the abdominal and vaginal methods of performing hysterectomy in cases other than malignant disease and general suppurative peritonitis. He would admit that the danger of hernia was a real objection to the abdominal method, but he would not admit that it occurred in capable hands in six per cent. of the cases. The argument that the patient could not get out of bed within a week after vaginal hysterectomy had no weight with him, for he did not believe that any woman should be allowed to get up inside of a month whose condition had been bad enough to demand hysterectomy at all. A strong objection against the vaginal method was the fact that it was more difficult, and required a third longer time during which anæsthesia had to be continued. As to the dangers, Dr. Jacobs had given a list of four hundred and three cases with nine fistulæ, while Dr. Baldy could cite two hundred and thirty-four cases by the abdominal method with no fistulæ. Because of these fistulæ Dr. Jacobs had been compelled to resort to two of the most dangerous of all operations. By the abdominal route one would never remove the pregnant uterus and not know that pregnancy existed, nor would he do a bilateral operation for unilateral disease of the appendages. Nor did one fail to complete the operation by this route, whereas all the gentlemen accustomed to doing vaginal hysterectomy had admitted to having left a part of the tissues which should have been extirpated.

As to the relative mortality, Jacobs had given a series of vaginal hysterectomies by himself, Péan, and others, with a mortality of 4.6 per cent. out of 724 cases. In strong contrast with this he could quote 224 operations by the abdominal route performed by such American operators as Polk, Pryor, Krug, Penrose, and Kelly, with a mortality of only 2.7 per cent.

DR. W. M. POLK, of New York, said the vaginal method was not at all recent, but it had been made practical since its first introduction by the experience which men had had in perfecting suprapubic work. Any person who had become expert with the latter could do the former successfully. Regarding conservative work on the appendages, even this could be done through the vagina provided one made his approach between the vagina and bladder so as to bring the appendages well within reach. Yet, owing to a fixation of the uterus in the upper part of the pelvis, one was liable to meet with disappointment in about half the cases. By the abdominal route all could be reached. Small ovarian growths, with comparatively few adhesions, and situated in the lower portion of the pelvis, could be most easily removed from below, although the mortality-rate was small by either method. There might be a difference of opinion as to the necessity of sacrificing the appendages in all cases of hæmatosalpinx and hydrosalpinx, but none in cases of pus collection, and inasmuch as the uterus was no longer of service without the appendages many believed it should also be removed. This was the class of cases, he thought, which Dr. Baldy had had chiefly in mind, cases of ovarian abscess, pus tube, and perhaps peritoneal pockets of pus. The adhesions might be very extensive. The cases could be separated into two classes, those in which the tubes and ovaries were so diseased that they were practically useless, yet were comparatively free from adhesions, and vaginal hysterectomy was very simple; and those in which the adhesions were great and would make the operation very difficult. Here he thought evacuation of the pus cavity and drainage by the vagina would be safer, leaving a more radical operation for a later date.

Regarding puerperal cases, Dr. Polk believed that when the case had reached the stage where operative interference was indicated the infrapubic route would be attended by much less shock, which was an important factor to be avoided in these cases. Owing to the relaxed condition of the pelvic organs after

pregnancy they could be removed more quickly through the vagina than from above. The speaker regarded the suggestion of Dr. Henropin as of very great value, namely, to make vaginal incision early in cases of pelvic inflammation where there was reason to believe that it had passed beyond the uterus.

As to the method of doing vaginal hysterectomy, Dr. Polk expressed his preference for the use of ligatures on the lower vessels, reserving clamps for a later stage, in order to acquire all possible room.

Dr. S. C. Gordon, of Portland, Me., conceded the brilliant results claimed by Dr. Jacobs and other experts in operating from below, and he had practised that method to some extent himself, but must express his preference for the suprapubic operation. He thought one could do better by sight aided by touch than by touch alone. He thought it was objectionable to pull down the ovaries and examine them, as Dr. Polk had recommended; they could not be returned to their former position if one should decide not to remove them. Then one could repair existing fistulæ much better from above.

Dr. W. Gill Wylie, of New York, said he had not performed vaginal hysterectomy in a very large number of cases, about fifty-five, and the results had been better, so far as the mortality was concerned, than by suprapubic hysterectomy, there having been only one death, but he did not believe they would have been better had the cases been of a similar nature. In private practice his mortality-rate by the suprapubic method would, at present, hardly exceed one per cent.; even in Bellevue Hospital it would not exceed three per cent. He regarded the vaginal procedure as much more difficult where the adhesions were high, and he doubted whether he should ever adopt it in that class of cases; the future would have to decide which method would give the best results. General surgeons would probably prefer the abdominal method.

Dr. Joseph E. Janvrin, of New York, had limited most of his vaginal work to cancer of the uterus and to removal of such fibroids as did not require hysterectomy. He thought that in tubal pregnancy, if the condition were recognized early, there should be no disease in the opposite tube, and hence there could be no necessity for its removal, and with it the removal of the uterus.

Dr. McGonigal, of California, maintained that it was not justifiable to remove the uterus for salpingitis without pus. Where pus existed it was justifiable to do complete castration, either from below or from above, but he had only practised the latter method. He thought it was a matter of personal judgment as to which route should be chosen. He agreed with Dr. Baldy, that fistula was much more likely to occur in operating from below, for out of seventy-two suprapubic hysterectomies the speaker had not had fistula of the bowel once.

Dr. William T. Lusk, of New York, thought that all were agreed as to operating from below where it was necessary to remove the uterus for cancer and for fibroids of medium size. In the case of pus tube, as long as there was a probability in a given case of its being unilateral, he would prefer to follow Dr. Polk's practice of saving the appendages on one side, together with the uterus. Regarding tubal pregnancy, he had operated upon a good many cases, and could not recall one in which the tube and ovary which had been allowed to remain had undergone disease, with the exception of one case in which carcinoma developed three years afterward, quite independently of the tubal pregnancy. Not approving, then, of Dr. Jacobs's recommendation, to remove the uterus in tubal pregnancy, he would prefer to operate from above.

A great deal had been said about operating from below in inflammation with supposed collection of pus. In talking to the family physician he found this gentleman was afraid to give morphine through fear it would mask symptoms; he was afraid to give an antipyretic for the same reason; he must not apply a blister, he must not use alcohol, he must only give something with a view to killing bacteria, or preventimg the development of streptococci, until a gynecologist could be sent for and operate upon the patient. Dr. Lusk thought we should remember that in this class of cases those recently confined and having a little afternoon temperature would, ninety-six times, he might say ninety-nine times in a hundred, recover if let alone, whereas if we undertook an operation we assumed a great responsibility.

Dr. H. C. Coe, of New York, said a point alluded to by Dr. Lusk had been impressed upon his mind very strongly within the past three weeks by being requested in three cases, in the event that an operation were decided upon, that it be done only through the vagina. Patients were becoming educated in gynecological matters, and many of them absolutely refused to have laparotomy, but would submit to a vaginal operation. He agreed with Dr. McGonigal that strong and high adhesions often complicated disease of the appendages and an exact diagnosis could best be reached after opening the abdomen. None of the speakers had referred to supplementary hysterectomy. He had been compelled to resort to this in four or five cases, operated upon three or four years before by removal of the diseased appendages, but which had not given relief. In such cases nothing was easier than to remove the uterus through the vagina.

Dr. Elv van de Warker, of Syracuse, indorsed the views expressed in Dr. Henrotin's paper, and said his own paper, to be read next day, contained a case showing the advantage of early vaginal incision.

Dr. Jacobs made some concluding remarks in French, Dr. Henrotin acting as interpreter. He said discussions were much more interesting here because Americans were much ahead of Europeans in this variety of work. They were slow in adopting new measures in the old country. Whatever might be the immediate results of the two methods of operating, he thought that if one would follow his cases for months or years after abdominal section, he would find that they were not as well off physically and mentally on account of the presence of the scar as they would have been had the vaginal method been adopted.

Drs. Henrotin and Wathen also made some closing remarks.

The Treatment of Puerperal Eclampsia.—Dr. Thaddeus A. Reamy, of Cincinnati, in a paper on this subject, related about half a dozen cases of puerperal eclampsia which were treated successfully by large doses of Norwood's tincture of veratrum viride, or by this agent combined with morphine. Most of the patients had been treated unsuccessfully by other means before he was called. Nothing could have been more striking than the promptness with which the convulsions had been arrested as soon as the veratrum viride had had time to act upon the heart and vaso-motor system. It had been shown by Dr. Jewett, in 1887, to be one of the most potent spinal and arterial depressants. It produced general vaso-motor paralysis. The advantage of the agent went further than to arrest the convulsions, for it produced copious perspiration and diuresis, and thus rid the system of the toxic ingredients producing the convulsions. The patient could take half a drachm of the tincture without danger, and he had given twenty-five minims hypodermatically. If alarming symptoms developed, they could be counteracted by morphine. It had been said that blood-letting would accomplish the purpose, but it was less effectual, was not without danger, and deprived the patient of blood which she would need afterward.

The Prophylaxis and Treatment of Puerperal Eclampsia.—Dr. Edward P. Davis, of Philadelphia, read the paper. Three or four cases were related, in which, as soon as nervous symptoms, headache, etc.,

developed, pointing to toxæmia which was likely to result in eclampsia if allowed to go on, he instituted treatment by calomel, hot pack, etc., increased the flow of urine and the function of the skin and bowels, and thus obviated convulsions. There might be no albumin in the urine, yet the diminished secretion, resulting in retention of toxins, would lead to headache, restlessness, sleeplessness, apprehension, even melancholia and mania, and finally to eclampsia. Physicians should learn that no progress could be made in the treatment of such cases by bromides. The excretions must be augmented. One should make a careful study of the urine during pregnancy, especially as to the quantity of urea and entire solids. It was a great mistake to suppose that the pregnant woman could be in no danger as long as the urine was not highly albuminous. In many cases of eclampsia or threatened eclampsia, it contained no albumin or very little. As soon as eclampsia set in there were two indications, one being to promote copious elimination, the other to empty the uterus. The poison which threatened the mother often killed the child.

Dr. W. T. Lusk said his own experience in puerperal eclampsia had been chiefly of interest in speedily emptying the uterus.

Dr. Lapthorne Smith, of Montreal, thought that as soon as there was the slightest danger of puerperal eclampsia, the uterus should be emptied. Whenever the urine was much diminished in quantity and was loaded with albumin, he thought it was almost criminal for us to remain idle when we had a means of putting the woman's life in safety. The best diuretic was plenty of water.

Dr. George J. Engelmann, of St. Louis, highly approved of prophylaxis. The urine should be examined frequently and appropriate treatment adopted for increasing its quantity if necessary. He had seen it contain so much albumin as almost to completely coagulate, yet the woman was carried to term with safety without inducing labor.

The President thought the question was one of renal insufficiency rather than of albuminuria. In many cases the urine contained no albumin until after the first convulsion, but it had contained a much smaller amount of solids than it should. In other words, the kidneys were not doing their work, and he knew no better plan than that recommended by Dr. Smith, of having the patient drink large quantities of water. This was the best prophylactic. The President also related some interesting experience with veratrum viride, which confirmed Dr. Reamy's views of its efficacy and safety in large doses.

The Ultimate Results of Trachelorrhaphy. — Dr. Willis E. Ford, of Utica, read a paper with this title, but explained that it would refer to only one of the ultimate results of trachelorrhaphy, namely, the effects of the operation upon nervous disorders. A great many nervous disorders, termed reflex, had been attributed to laceration of the cervix, and an operation had been done largely with the object of relieving such nervous symptoms. But the author held that the term reflex had been much abused, that about the only way in which a reflex was produced was through convulsive or spasmodic symptoms, and that where trachelorrhaphy had benefited the nervous symptoms it was only indirectly, by improving the general health. He had collated 136 cases of his own in which the condition of the patient was ascertained at least a year after trachelorrhaphy; 60 had not presented any unusual nervous symptoms, as the operation had been done for the usual condition of ill-health and pelvic pain caused by erosion. In all of these the ultimate result had been all that one could ask. In the other 76 there had been marked nervous disturbance, the condition of neurasthenia having brought the patient to the physician. The operation on the cervix had been followed by good union and by involution of the uterus. In 49 the nervous symptoms disappeared under proper treatment carried on for a year; in 27 there was no marked change produced by the operation. In 2 of the latter he finally removed the appendages for actual disease of the ovaries. Twenty-five, therefore, remained uncured after the lapse of a year. Thus it appeared that a well-marked nervous disorder which had become established would not be removed by trachelorrhaphy. The reason lay in the fact that hysteria, neurasthenia, and other nervous disorders of which these patients complained, were of deeper origin than peripheral irritation.

Dr. Clement Cleveland, of New York, thought failure to cure the patient's nervous disorders was often due to the operator directing his attention only to the torn angles, and failing to amputate the anterior and posterior lips as well.

Dr. G. J. Engelmann, of St. Louis, had seen pain in the back and disturbance of digestion disappear immediately after operating on the lacerated cervix. He would call such a nervous disorder reflex. He curetted the uterus, as there was apt to be also endometritis, and trimmed the cervix, doing so-called amputation.

Dr. A. F. Currier, of New York, said there were two classes of cases: 1, Those in which there was not much the matter with the cervix, yet the operation resulted in marked benefit through emotional influence; 2, those in which there was much tissue injury and change, resulting in excruciating sensations in various parts of the body and sometimes in exhaustion. Here the operation was essential, and gave excellent results regardless of the emotional influence.

Dr. A. Palmer Dudley, of New York, thought the ultimate results of trachelorrhaphy would depend upon one's selection of cases and the manner in which he performed his work. He formerly operated upon nearly all cases, but for some time he had abandoned the operation nearly altogether and directed his attention to the relief of the condition higher up. Nor did he perform amputation of the cervix, for this would destroy the proper balance of the upper and lower portions of the uterus and favor displacement. A free canal was essential to healthy condition of the parts, and many operators had caused salpingitis by narrowing the cervix in performing trachelorrhaphy.

Dr. S. C. Gordon, of Portland, Me., like Dr. Dudley, had seen extremely bad conditions of the appendages follow trachelorrhaphy in many cases, so that he now almost dreaded to see the operation done. The treatment should be: Dilate the cervix, curette the uterus, wash it out, and repeat this treatment until the canal became permanently patulous and involution had taken place. He had not performed trachelorrhaphy twice the past two years.

Dr. George T. Harrison, of New York, claimed that trachelorrhaphy was a most valuable operation, but it had often been wrongly performed, and in cases in which it was not indicated and for the relief of symptoms not due to cervical laceration.

Dr. Homan spoke favorably of trachelorrhaphy, even in minor tears, although it must be done in a proper manner. It prevented and relieved many disorders relating to digestion, etc., showing their direct or remote relation to the cervical lesion.

The discussion was closed by the author.

A Few Cases of True Pelvic Cellulitis: A Plea for More Thorough Pelvic Surgery.—Dr. Ely van de Warker, of Syracuse, read this paper. The time had now arrived when we knew what pelvic cellulitis was as well as what it was not. This form of inflammation might exist alone, or it might exist in conjunction with inflammation of the pelvic organs. It might be present high in the pelvis, or it might extend down and involve the cellular tissue between the vagina and rectum. Unless the latter existed in marked degree, it was not likely to be detected by vaginal examination

alone. Combined rectal and vaginal examination was necessary. It should be looked for as a possible complication of other forms of pelvic inflammation. The superiority of vaginal hysterectomy over abdominal operations was due largely to the more perfect and wide drainage secured for all the pelvic tissue.

The paper was discussed by Drs. Lapthorne Smith, J. W. Williams, M. D. Mann, A. P. Dudley, Etheridge, Wylie, and the author.

Dr. Williams said it was seldom that one had opportunity to confirm the diagnosis of uncomplicated pelvic cellulitis post mortem, but he had seen two such cases in women who had died of symptoms of sepsis in childbirth. He was sure, however, that the vast majority of cases of pelvic suppuration had their origin in the tubes and ovaries.

The Prevention of Uterine Disease due to Childbearing.—Dr. W. Gill Wylie, of New York, read the paper. It advocated more extended resort to induction of labor by men who had become expert in their profession and knew how to observe strict antisepsis. Where the pelvis was not large, and where the cervix was hard, he did not hesitate to induce labor. The position of the child could be determined before labor, and if it was not what it should be, do external version. After trying the different methods of inducing labor, he had returned to the soft gum catheter, leaving it in over-night. The woman should be put in the best possible condition preparatory to childbirth.

The next point was the treatment of sepsis. If just after the first chill one would remove all large pieces in the uterus with the forceps, then curette, wash out, and introduce gauze, the sepsis might be stopped at once. But where the infection had gone further, this was not sufficient. Then to keep the gauze in twelve or twenty-four hours would serve only to increase the infection, and to force the septic material into the tubes and sinuses. The septic material might be limited to the interior of the uterus for two or four days. Where the sepsis continued, he washed the uterus every hour. After the tenth day following labor he kept the uterus up by boroglyceride cotton pledgets, left it in twenty-four hours, and repeated it twice a week.

Dr. A. P. Dudley, of New York, thought we were giving dangerous advice in recommending a frequent resort to premature labor, for the men who saw the vast majority of cases of confinement did not understand antiseptic surgery as well as gynecologists. Since sepsis was most likely to occur through injuries, Dr. Dudley attempted in all cases to immediately repair injuries of the uterus and vagina, as well as of the perineum. It could be done in abortion as well as in cases of labor at term.

Dr. H. P. C. Wilson, of Baltimore, said he had never used the curette after labor. He thought the fingers were much safer, and gave more exact information. Nor did he pack the uterus. It was better to leave the canal quite open and thus favor free discharge. Wash out the uterus four or five times a day if necessary. Give the patient good nourishment. Observe strict cleanliness.

Dr. W. T. Lusk, of New York, believed that most cases of puerperal sepsis started in the interior of the uterus. Streptococci were present, and in order to prevent these from penetrating the mucous membrane, white corpuscles were thrown out and formed a barrier. This was Nature's way of doing the work, and if we would let her alone we would have not nine cases out of thirteen recover, but thirteen. If, on the other hand, we curetted, we would break down Nature's barrier, and although some cases would survive, yet we would lose some which ought to have gotten well.

Dr. Williams, of Baltimore, expressed delight on hearing Dr. Lusk's remarks, for they were in harmony with his own observations and teaching. That was one class of cases. There was another in which there was necrotic material on the surface of the uterus, containing putrefactive organisms, in which the material needed to be removed mechanically and then washed out with boiled water, which was just as good as bichloride or carbolic acid, and was unattended by risk of poisoning the system.

Dr. J. M. McCoble, of Texas, invited guest, said he had found that injections of water or carbolized solution were not sufficient to bring away all the shreds of membrane and prevent recurrence of chills, and had consequently swabbed the uterus with borated cotton on a probe.

Dr. Wylie said he would not have proposed more frequent induction of premature labor fifteen or twenty years ago, when our knowledge of antisepsis was much more limited. Washing out the uterus every three or four hours gave the germs time to develop during the intervals. He had cured cases abandoned as hopeless after having been treated by this method, and had cured them by washing out every hour.

Deciduoma Malignum.—Dr. J. Whitridge Williams, of Baltimore, described a case of this rare affection, the first, he said, which had been fully reported in this country. Since Sänger's first case in 1888 the entire number of cases reported amounted to about thirty-four. According to the exact site of the disease on the placental structure or uterus, different names had been given, but in all instances it was malignant, and he therefore approved the general term deciduoma malignum. In his own case, seen with Dr. Harris, it could be classed as a carcinoma of the uterus, not a sarcoma, as it would have been had it been derived from the decidual cells as in Sänger's case. The two forms were closely allied; indeed, in some cases they seemed to be mixed, and gave the same clinical history. It occurred most often in young women, usually after full term or abortion, and at least half the cases had followed hydatidiform mole. They ran a rapidly malignant course. Death usually occurred within six months—in his case within three months; there was apt to be metastasis, and this had shown itself in his case on the vulva two weeks after labor. The only efficient treatment would be early recognition of the disease and prompt hysterectomy.

Some Points in Symphyseotomy.—Dr. William T. Lusk showed some diagrams in illustration of Pinard's method of performing symphyseotomy.

Dr. Kelly read a letter from Dr. Robert A. Harris, of Philadelphia, stating that he could not be present to read his paper on "Symphyseotomy in Canada and the United States," but sending the paper and giving the reasons for preferring the spelling "symphyseotomy," instead of "symphysiotomy."

The Value of Gauze Drainage.—Dr. H. C. Coe, of New York, in a paper with this title, referred to the history of drainage in general, and the fact that the indications were now more strictly defined than formerly. He would consider only two applications of drainage, namely, of the uterus and of the pelvic cavity. Having been led to believe that the value of gauze as a drain had been exaggerated, he had addressed circulars to a number of prominent gynecologists, and had found that there was a wide difference of opinion among men whose results were equally good. Many had the utmost confidence in gauze, which they used almost exclusively, others preferred tubes, and a third class rejected drainage entirely. But it was curious that some of the latter always inserted gauze into the uterus after curettage, even in non-septic cases. It was not the writer's purpose to seek to depreciate the value of gauze in pelvic surgery, but rather to seek to decide the question what it accomplished: whether it acted as a true drain, or merely as a tampon. The action of gauze when introduced into the uterine cavity differed according to the size of the cavity and the condition of the muscular walls. If the latter were flabby, it stimulated the organ to contract. After curettage and irrigation of the non-septic uterus this was its principal function. There was cer

tainly nothing to drain away except blood and serum, and so far from maintaining patency of the canal, it rather plugged the os and prevented fluid from escaping, so that drainage was more free after removal of the gauze.

As a hæmostatic in abortion and after removal of neoplasms, the gauze acted purely as a tampon, besides favoring uterine contraction. In septic cases, puerperal and non-puerperal, it was only serum which escaped through capillary drainage. Fragments of decidual membrane, etc., were expelled after removal of the gauze. It was frequently noticed that the hoped-for fall of temperature after curettage only occurred after the tampon was withdrawn.

Dr. Coe believed that thorough irrigation with peroxide of hydrogen after curettage was followed by as good results as when the tampon was used, or even better. With regard to drainage of the pelvic cavity with gauze, he believed it had grown in favor on account of the increasing popularity of the vaginal route. In vaginal hysterectomy, however, gauze was to be regarded as a tampon rather than as a drain. It was used in abdominal surgery for three purposes, namely: 1, To cover extensive raw surfaces, both to check obstinate oozing and to prevent intestinal adhesions; 2, to isolate septic foci from the general peritoneal cavity by favoring the formation of adhesions; 3, to drain away septic fluids.

That septic material was removed to any extent by capillary drainage was doubtful. Certainly, thick pus, fibrinous exudates, and sloughs were rather prevented from escaping by the presence of tampon. Drainage took place, the first twenty-four or thirty-six hours of thin serous fluid which might constitute a favorable nidus for germs. The most rational way of favoring such drainage was to maintain a free opening in the vaginal roof. Thorough drainage through the abdominal wound could not be expected.

In short, the reader believed with Sawyer, that the expression "gauze drain" was a misnomer, since we should speak rather of the "gauze tampon." The following practical deductions were made: 1. The introduction of gauze into the non-puerperal uterus as purely a drain is unnecessary, and even objectionable. 2. The gauze tampon, with a large, flabby septic uterus, after curettage promotes contraction of the organ, but often prevents the escape of septic matter, which is expelled only after removal of the gauze. 3. Tamponade of the pelvis with gauze is an invaluable means of arresting obstinate general oozing. 4. The gauze not only prevents the formation of intra-pelvic intestinal adhesions, but favors the development of plastic lymph around septic foci, thus shutting them off from the general cavity. 5. Capillary drainage with gauze, especially per vaginam, serves to remove a certain amount of serum which might form a nidus for germs, but little septic material beside.

Dr. William M. Polk, of New York, was elected President.

Scientists are now telling us that the dangerous microbe is lurking in the bank-note. Those in arrears for subscription can send the amount to Southampton Street, as we have the facilities to disinfect fivers, and are willing to take the risk.—*Tit-Bits.*

An Open-air Thinker.—At a Helmholtz memorial meeting in Berlin, in speaking of his genius, Dr. von Bezold said that the new ideas which did so much to advance science never came to him in his room, but always on his walks in the open air.

An International Congress for the Protection of Infancy will be held at Bordeaux next August. Beside the moral, legal, and physical sides of the subject, it will discuss the decline of parental authority and its delegation into other hands.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE GENERAL MEDICAL COUNCIL — PENAL COMMITTEE—REPORTS—MIDWIVES' BILL—OBSTETRICAL SOCIETY'S SO-CALLED DIPLOMA—THE OPIUM QUESTION —OBSTRUCTION OF PANCREATIC DUCT — GRAVES'S DISEASE — RELATION OF ULCERATIVE COLITIS TO SWINE-FEVER.

London, May 31, 1895.

The General Medical Council opened its session on Tuesday, and is still sitting. The President (Sir R. Quain) gave an address as usual, in which he foreshadowed, so to say, the work of the session, and related what had been done by the Executive Committees since the last meeting. A prominent point in the address is the coming issue of a new pharmacopœia, and the steps taken to insure that it shall be worthy of its predecessors and of the Council.

No less than 21 charges of misconduct by registered practitioners have been lodged since the last meeting. They have been investigated by the Penal Committee, aided by the solicitor, and 15 have been set aside, the other 6 being summoned to appear and defend themselves. One of these being in Australia is summoned for the November session. The usual reports from public bodies and from committees were forthcoming, and their consideration occupied some time. It was also reported that the reversion to the freehold of the premises had been purchased. A proposal to vary the allowance of travelling expenses for members coming long distances was negatived. Another proposal to give more time to the work of the Council, viz., three hours in the morning and three in the afternoon, met with scanty support, although members from a distance would be glad to curtail the period of their absence from home. Other members, however, did not see any need to reduce the fees they draw for attendance, so nothing was done.

The midwives question, of course, came up in acute forms. A deputation of practitioners from the North of England was received, and urged upon the Council strong views against the bill now before Parliament, which it was feared would only tend to establish a new and inferior order of female practitioners and prove a fruitful source of injury to parturient women. This proposal to register midwives is still supported by a number of consulting accoucheurs, but is most obnoxious to general practitioners, who see in it injury to the profession as well as to the public.

The government has asked the Council's opinion on the bill, and as differences exist within that sacred precinct the debate is the most important of this—which may, perhaps, be known as the midwives' session.

The Obstetrical Society has rather caved in after all the bluster of its officers about the Council's threat to consider further issues of its objectionable so-called diploma as "infamous in a professional respect." The Society has agreed to modify its certificates in a manner which has been accepted by the Executive Committee of the Council. The new form, however, did not meet with the approval of all and some warm discussion ensued, but the Council was not willing to reject the decision of its committee. In some form or other this question must be more thoroughly threshed out. There ought to be no compromise. The Society has no more legal right to issue anything of the nature of a diploma than a club or a board of directors of any company. The Society has gone on for years in its unprofessional diploma-selling and it is high time to put it down. What is the use of compromise on such a question?

As I predicted the report of the Opium Commission

has not convinced some of the ardent opponents of the cultivation of that drug. The question has been before the House of Commons this week on a motion of Sir J. Pease, who made rather a bitter and unjustifiable attack, descending even to personalities, on the Commission. The minister had no difficulty in replying and rejecting the motion in dignified terms, and the House supported the ministry by a large majority.

The session of the Pathological Society closed on the 21st with the annual meeting, at which the officers were elected for the coming year. The report showed the Society to be in a prosperous condition. There was a serious paper, embodying the result of some careful analyses, by Dr. Vaughan Harley, on "Abortion and Metabolism in Obstruction to the Pancreatic Duct." In cases of obstruction of the pancreatic flow the fat absorption in man was diminished to 26.95 per cent., while in the case of dogs with partial removal of the pancreas four to thirty-seven per cent. of the fat given was absorbed. Still further, in the case of dogs in which the pancreas had been entirely removed no fats whatsoever were absorbed in the space of seven hours. As regards the proteids twenty-two to fifty-three per cent. of the proteids given were absorbed in dogs; while when the animal had considerably lost flesh only seventeen per cent. were absorbed. In the boy's case sixty per cent. of the proteids given were absorbed, but the body weight was unable to be kept constant. Dr. W. Edmunds brought forward some observations and experiments on the "Pathology of Graves's Disease," from which he concluded that accessory thyroids were extremely active functionally and were not merely embryonic. The symptoms of Graves's disease were due to some form of nerve disease rather than to a secretion from the diseased thyroid, because (*a*) thyroid feeding or thyroid extract would not cause exophthalmos, (*b*) but the eye symptoms could be produced by stimulation of the cervical sympathetic and were therefore certainly of nervous origin. The enlargement of the thyroid could be explained by stimulation of the sympathetic. All the symptoms of Graves's disease could be produced by an artificial lesion of the brain, and all the symptoms, including the enlarged thyroid, could be produced temporarily by mental emotion.

Mr. Leopold Hudson exhibited a series of recent specimens of the large intestine of pigs which were affected with swine-fever to illustrate the similarity of distribution between these lesions and the conditions in the human being which had been described as simple or general ulcerative colitis. The ulceration was confined to the cæcal aspect of the ileo-cæcal valve and to the large intestine, and every stage could be found, from the small simple ulcer to the large confluent areas of destroyed mucous membrane with adherent masses of necrotic tissue. In the human being the distribution of the ulceration was similar, though the naked-eye appearances were different owing to differences in gland structure in the human and pig's intestine. The similarity between the disease in swine and in mankind, both as to morbid anatomy and described clinical symptoms, certainly seemed to justify inquiries as to their possible intercommunicability.

Dr. Rolleston said that the specimens shown did not seem to resemble the cases of ulcerative colitis he had seen in the human subject, in that in the latter large areas of necrosis did not occur, and he thought that in the swine there was not such a tendency to perforation.

Dr. Herringham said that in some cases in human beings necrosis occurred.

Dr. Voelcher said that in a case of ulcerative colitis which he had examined there were large patches of acute necrosis of the mucous membrane.

Professor Cope, chief veterinary officer to the Board of Agriculture, said that in an early case all that would be found were small hyperæmic spots in the mucous membrane of the intestine; after that infiltration took place and a central area of necrosis formed. The ulcers might remain discrete and isolated, but very frequently they became confluent. Two common pathological varieties of the disease were met with—the ulcerative and the diphtheric. Two good instances of the latter variety were shown.

Mr. Hudson, in reply, remarked that experiments were about to be performed by inoculating and feeding pigs with ulcerative colitis from human beings, with a view to discover if intestinal lesions could be thereby produced. The colon of the pig contained a number of glands precisely like Brunner's glands in the human duodenum, and ulceration and infiltration of these produced the peculiar "button" ulcers of swine-fever.

Mr. Herbert Snow read a paper on "The Malignant Reversion of Mammary Cystic Fibroma."

MAX NORDAU: A REPLY TO MR. HOWELLS.

To the Editor of the Medical Record.

Sir: A short while since there appeared in *Harper's Weekly* a criticism by Mr. Howells of "Degeneration," the recently translated book of Max Nordau. Of all the *critiques* of the work that have come under my observation, Mr. Howells's seems to me to be the most unjust, the most unfair, and the most trivial. When one criticises a scientific work, characterizing it as nonsensical, purposeless, and the work of a crack-brained idiot—for this, in substance, is what the above-mentioned criticism amounts to—one should support his conclusions and assertions by arguments in which proofs warranting such conclusions and assertions are adduced.

I will ask any unprejudiced reader to carefully read the criticism of Mr. Howells and see if he can discover a single argument brought forward in support of the assertions and assumptions comprising the mass of the subject-matter making up the article under discussion. I failed to find *one*, though I read the communication with great care at least three times!

Mr. Howells is not a scientist, therefore is content with supporting his propositions by simple assertion. He likewise makes the usual illogical mistake of a superficial observer, that of characterizing as nonsensical that which he cannot comprehend and appreciate. Far be it from me to call in question the mental acumen of the successful (from a financial point of view) novelist, poet, and essayist. Mr. Howells's bank account will doubtless show that his financiering faculty is all right and that he is not a victim of degeneration, at least in this respect. Nor is it my purpose to write a criticism on his works, for, with the exception of "The Rise of Silas Lapham" and certain socialistic papers met with and cursorily scanned in the magazines, I am in complete ignorance of his writings.

I confess that I like originality, and, to me, Mr. Howell is not original. I read a novel for the intellectual amusement it affords—I study an essay on the social problems of the day for the knowledge it may instill. To me Mr. Howells's novels are not intellectually amusing—his social essays bring no additional knowledge, for they are twice-told tales. But this is another matter; that which I have directly in view is a study of Mr. Howells's attack on Max Nordau and his book. He first pays his respects to Professor Cesare Lombroso, Professor of Legal Medicine and Psychiatry, University of Turin, the foremost authority on forensic medicine in all Europe. Speaking of Nordau's advocacy of Lombroso's theories Mr. Howells says: "The richness of his find will not be surprising to anyone who knows the Lombrosian theories and methods, *and has witnessed the ease with which the good Professor discovers whatever he looks for.*"

This of a man who is known and respected throughout the entire scientific world and whose honesty has

never before been questioned! Mr. Howells should have included, Charcot, Binet, Féré, Ségelâs, Séguin, Dana, Ellis, and dozens of other noted men, all smitten with Lombrosian madness, in his pitiful little witticism. But why call it Lombrosian? Surely an omniscient critic like Mr. Howells must be aware of the fact that the germs of the Lombrosian theories were discovered and enunciated over seventy years ago?

In the "Delinquent Man" (I use Mr. Howells's translation of *L'Uomo Delinquente*) Lombroso carefully gives the credit to those to whom it is due. He was not ashamed to borrow the ideas of other men, nor was he ashamed to acknowledge the sources from whence he derived his inspiration. The critic accuses Nordau of borrowing. I grant that he is correct, and so will Dr. Nordau, for he begins his prefatory letter thus:

"Professor Ceasare Lombroso, Turin.

"Dear and Honoured Master: *I dedicate this book to you in open and joyful recognition of the fact that without your labours it could never have been written.*"

In my opinion there could not be a more honest confession. Virgil borrowed the incidents, I might even say the plot of the "Æneid;" Shakespeare borrowed the plots of "King John," of "Romeo and Juliet," of "Timon of Athens," and of several others of his plays; Robert Fulton borrowed the ideas and the plans of James Rumsey, and yet the genius of these men cannot be questioned nor their fame lessened. Let the altrurian glance over his own altruistic (socialistic) works and see if he has any right to cry, "I am more holy than thou!" I do not mean to imply by the context that I consider Mr. Howells a man of genius. He has unmistakable talent, but I fail to discover any evidence of genius.

Richard Grant White says somewhere that "Genius is mainly an affair of energy;" substitute the word talent for genius and I will heartily concur and agree with Mr. White. No one can deny that Mr. Howells has a superabundant amount of energy, for does he not himself inform us that he has written some thirty or forty books? Ye gods and little fishes! a whole library, and, judging from appearances, he is yet far from death. But let us return to our mutton.

Speaking directly of Dr. Nordau he accuses him of insincerity and declares that "he is only a clever quack advertising himself." This of one of the most noted literary critics, psychologists, and neurologists in all Europe!

This seems to me to be rather unfair criticism, coming as it does from a man who puts a premium on his autograph, for does not Mr. Howells declare, through Mr. Bok, that he will not send or give his autograph, "with a sentiment," to any one, unless the applicant furnishes evidences that he has read all of his (Mr. Howells's) thirty or forty books? Continuing, if I am not mistaken, he declares that a "bookseller's certificate to the effect that the books have been purchased will be considered the best evidence." Long head! Level head! The financial faculty shows no signs of degeneration.

I wonder what the dignified and scholarly German, whom the critic attacks so bitterly, would say, were such a proposal made to him? Mr. Howells sarcastically observes: "Not such monsters alone as Tolstoi, Ibsen, Zola, Ruskin, Wagner, Verlaine, Maeterlinck, . . . are captured as degenerates and shown as proofs of Dr. Nordau's second-hand hypotheses, but every realist, symbolist, moralist, mystic is equally useful to him." The implication in the above sentence is that none of these men show or showed signs of degeneration. Let us take the last name in the list, Maeterlinck, and see if this is true; for I can, fortunately, verify the truthfulness and exactness of Dr. Nordau's excerpts from the writings of this author, as well as the literalness and faithfulness of the Appleton translation. Says Dr. Nordau anent this unfortunate, p. 227: "As in Rollinat we have learned to know the poet of anxiomania" (frenzied anguish) "so shall we find in another author, whose name has become widely known in the last two years, in the Belgian, Maurice Maeterlinck, an example of an utterly childish idiotically-incoherent mysticism. He reveals the state of his mind most characteristically in his poems, of which I will give a few examples. Here is the first of the collection:

"'Serres Chaudes.

"'O hot-house in the middle of the woods, and your doors ever closed! And all that is under your dome! And under my soul in your analogies!

"'The thoughts of a princess who is hungry; the tedium of a sailor in the desert; a brass band under the windows of incurables.

"'Go into the warm, moist corners! One might say 'tis a woman fainting on harvest-day. In the court-yard of the infirmary are postilions; in the distance an elk-hunter passes by, who now tends the sick.

"'Examine in the moonlight! (Oh, nothing there is in the place.) One might say a mad woman before judges, a battleship in full sail on a canal, night birds on lilies, a death-knell toward noon (down there under the bells), a halting-place for the sick in the meadows, a smell of ether on a sunny day.

"'My God! my God! when shall we have rain and snow and wind in the hot-house?'"

Mr. Howells may consider this good, sound, sensible poetry, and its author a sane man. I do not. It seems to me I have heard its like time and again in the wards of lunatic asylums. In fact, I have several dozen poems similar in character and written by lunatics in my possession at the present moment. Further along, after giving numerous other poems, Dr. Nordau says: "Nothing would be easier than to compose others on these models, overtrumping even those of Maeterlinck—*e.g.*:

"'Oh flowers! And we groan so heavily under the very old taxes! An hour-glass at which the dog barks in May; and the strange envelope of the Negro, who has not slept.

"'A grandmother, who would eat oranges and could not write! Sailors in a ball-room, but blue! blue! Oh, two soldiers in the cowhouse, and the razor is notched!' etc.

"But why parody Maeterlinck? His style bears no parody, for it has already reached the extreme limits of idiocy."

The critic discourses tenderly and touchingly of Christianity and morals, yet castigates Nordau for daring to call attention to the insane sensuality of Paul Verlaine, who suffered a term of imprisonment for a crime against nature. I wonder that Mr. Howells did not put Oscar Wilde in his list of slandered immortals, since he is among the degenerates listed in Nordau's book. But why discuss Mr. Howells's paper any further? I think that I have shown that his *critique* is unjust, unfair, and exceedingly trivial. He, like a great number of his kind, has attempted to discuss a subject about which he knows little or nothing, consequently has been led into grievous error. Now one word about Max Nordau and his book. I cannot say that I agree with him in all of his propositions; for I believe that enthusiasm has carried him a little farther than he intended to go, and has led him into error. Yet I unhesitatingly say that I consider his book one of the most valuable contributions to the science of psychiatry that this century has produced.

James Weir, Jr., M.D.

Wayland.

MORNING DIARRHŒA.

To the Editor of the Medical Record.

Sir: To an *ensemble* of symptoms, of sufficient importance to merit independent notice, Dr. Delafield applies the term "morning diarrhœa." It will be unfortunate if any shall look upon the name as conveying the idea of a distinct malady, nor do we conceive this to be the idea of the accomplished physician who suggests the title.

This condition we recognize as a phase of intestinal dyspepsia, and, as a rule, sequel to catarrhal and dyspeptic disease of the upper digestive tract. It is most frequently met with in those who have suffered from deranged hepatic functions of malarial or other causation, and hence is more common in the South than in other localities. A large number of such cases have come under the writer's notice, which induces him to add this note to Dr. Delafield's interesting article.

In most cases the call to stool comes soon after waking, and is preceded by the passage of flatus, and often by a burning sensation in the rectum, indicative of the descent of acid fæces. The call may be so slight as to pass unheeded, or so imperative as to demand immediate attention; the motion consists of liquid and scybalous masses, malodorous, and, as a rule, not copious, the lower bowel being seldom effectually emptied.

The evacuation is followed by a sensation of faintness and discomfort of a burning character over the region of the lower bowels, which, as Dr. Delafield states, is often so severe as to incapacitate the sufferer for all the forenoon. Patients dread this after discomfort so much that many, by persistent effort, restrain the bowels, a pernicious habit, which often results in the condition of auto-infection described by Sir Andrew Clarke.

A second motion follows after breakfast, and possibly a third, the bowels remaining quiet in the afternoon and evening, unless a more acute condition has supervened.

Those who have suffered for any length of time present decided evidence of malnutrition and defective hæmatosis; the complexion inclines to sallow, the tongue is lightly furred or gashed, the appetite is capricious and uncertain. The nervous system is usually involved, sleep is disturbed and insufficient, memory is impaired, and the power of concentration or continued mental effort is diminished. These remarks apply to chronic cases, between which and the acute form there is much variety as to phase and extent. Often a slight but acute dyspepsia has preceded, and a tolerance of the symptoms becomes established without cure, the condition resulting in gastric dilatation with defective motility; the food passes the pylorus non-peptonized and uninfluenced by pancreatic digestion, in a septic and fermentescible state, to induce the symptoms predicted in the lower bowel, where of course eventually congestion and perverted secretion result. These conditions, superadded to deficient peristalsis and usually a restricted dietary, occasion ineffectual efforts at evacuation.

There are doubtless many cases, especially in city practice, of a more distinctly nervous form, such as are caused by undue fatigue, mental or physical, and in females with neurasthenia of menstrual origin. The writer is unaware of having encountered a case of this trouble in one from the country, although we know that dyspepsia abounds there, which is suggestive of the nervous element in the disease incident to urban occupation and environment.

As to prognosis, if change of environment and habits be undertaken sufficiently early the disease can be cured. Chronic cases are benefited, but seldom if ever eradicated. In almost all cases an ocean voyage is attended with marked benefits. An instance is recalled of an officer in the navy so seriously reduced by symptoms of this character that it was necessary to invalid him to the United States. A day or two out, great improvement rapidly began, and the patient was so fully restored before the end of his voyage as to feel much embarrassed on reporting at the hospital to which he had been ordered. Yet, while this rapid improvement occurs, as Dr. Delafield remarks, a return to the old environment brings a return of the disease. Likewise a change to the country is of the greatest benefit. In so far as diet is concerned anything beyond ordinary care should not be enforced; yet, as in most digestive troubles, vegetables are more difficult of digestion and more liable to fermentative change.

As to medicinal treatment, tonics are but of little service, and the best agents are those which arrest fermentation and produce antisepsis. Of these beta-napthol is decidedly the most valuable, and will arrest diarrhœa more speedily and permanently than opiates, which are rather to be avoided. Many cases are benefited by a draught of aperient saline water before breakfast, which insures flushing and thorough evacuation of the bowels. In advanced cases the depletion caused by such treatment must be borne in mind, and for these, as well as others, the best results are obtained from a prolonged residence at the springs, such as Vichy and Kissingen in Europe, the Allegheny Springs (Montgomery Co.) in Virginia, and Saratoga, N. Y.

THE CATHOLIC CHURCH AND OBSTETRICAL SCIENCE.

To the Editor of the Medical Record.

Sir: An article entitled "The Catholic Church and Obstetrical Science," in the Medical Record of February 2, 1895, page 147, has lately been shown to me, and I consider it my duty for the sake of Christian ethics and for the information of many members of the noble profession your periodical so ably represents to protest against the utterly loose and misleading statements it contains. The article is short and claims to be a summary of the views expressed by an anonymous writer in the "*Münchener Medicinische Wochenschrift*, with regard to the lawfulness of craniotomy. The objectionable statements, implied or explicit may be reduced to three: *a*, That Rome has never condemned craniotomy; *b*, that Catholic theologians, and in particular the Jesuit Father Lehmkuhl, are in favor of it; and *c*, that this operation in itself is not wrong, for it is demanded both by necessity and science.

To show how untenable these views are I might refer the reader to a letter published over my name in the Medical Record, November 28, 1885, page 606. But a few additional remarks, I am sure, will not prove unacceptable to the medical profession.

With regard to the attitude of Rome the "anonymous writer," as reported and summarized by the reviewer in the Medical Record, has the following: "The question was submitted whether craniotomy or any operation directly tending to destroy the life of the fœtus in utero was ever justifiable. The Sacred Congregation replied that "after mature deliberation it would advise the questioner to follow the most approved authorities, whether ancient or modern, and act prudently." Were this the only document promulgated by the Church in the matter of craniotomy, the inference made by the "anonymous writer" would not be entirely without reason. But this is another case of where not to tell the whole truth is just as bad as not to tell the truth at all. We have, as a matter of fact, four answers from Rome on this question. The first was given November 28, 1872, by the Sacred Penitentiary, during the first stage of the discussion. The

question, be it remarked, had been mooted only a little before that time by Dr. Avanzini, editor of the "Acta S. Sedis." This is the answer quoted by the "anonymous writer." The second answer was given December 10, 1883, to Mons. Dabert, Bishop of Périgneux, in France. In it Cardinal Bilio states that the Sacred Congregation of Inquisition is still examining the question, and has not yet reached a final decision. Here are his words: "The third doubt (proposed by you, and concerning craniotomy) being the subject of many inquiries made by other Bishops, is still under consideration by this Sacred Tribunal." The third answer is dated May 31, 1884, and was sent by Cardinal Monaco La Valletta to Cardinal Caverst, Archbishop of Lyons. The whole document runs thus: "The cardinals of this congregation have carefully weighed the doubt proposed by your Eminence, as to whether it would be safe to teach in Catholic schools that the surgical operation called craniotomy is lawful, when on the one hand mother and child will die, if recourse is not had to the operation, and on the other, if such recourse is had, the mother will be saved at the expense of the child's life. After long and mature consideration, after close scrutiny of the views advocated in this matter by Catholic men of science and submitted by your Eminence to this congregation, we think it incumbent on us to answer that 'It cannot be safely taught.'" Rome spoke for the fourth time on August 19, 1889, reiterating the same decision. The entire text of this document can be found in the "American Ecclesiastical Review," vol. ix., page 352. We content ourselves with the following short extract: "We, the cardinals in committee assembled, have come to this conclusion that in accordance with the declaration made on May 28, 1884, it cannot be safely taught in Catholic schools that the surgical operation known as craniotomy is lawful, and the same is to be said of whatever surgical operation aims directly at the killing of the fœtus or of the pregnant mother. I acquaint your Lordship with this decision that you make it known to the professors of the medical faculty of the Catholic University of Lille."

The very tenor of these answers, the way they have been accepted and understood by theologians and professors in all the Catholic Colleges and Universities, the injunction that they should be made known to the members of the medical faculty, and the admission therein contained that craniotomy is one of those surgical operations which are and must be called *directe occisivae*, truly murderous, preclude every other abstract and otherwise possible interpretation of the *Tuto doceri non posse*, except the practical one, *i.e.*, that craniotomy is unlawful, morally unlawful, always and intrinsically unlawful. In addition to this I may remark here, what I stated elsewhere more fully, that an opinion which cannot safely be taught will never be held as probable by Catholic theologians. Hence it follows that, as a solid probability is certainly required for an act which is *prima facie* murderous, no Catholic will ever be allowed to connive at, and still less to perform, the surgical operation of craniotomy. Rome indeed could not have spoken more clearly, and when we reflect that her utterances have been public property for the past ten years, one cannot but be surprised that the "anonymous writer," dignified by the editor of the *Münchener Medicinische Wochenschrift* with the title of "inspired," failed to give them a place in his article. Inspiration is a term that admits of many meanings, but we had always thought it too sacred a thing to be confounded with ignorance. That the "anonymous writer" derived his inspiration, in this instance, from ignorance is a conviction that must force itself on any honest reader; for we cannot suppose for a moment that malice could have ever moved his pen.

The varying stages of controversy through which this question has passed, and the prudent circumspection of Rome in the premises are sufficient explanation of the stand taken by theologians at successive intervals. Father Lehmkuhl and others during the first period of discussion admitted doubts and ventured tentative solutions, but afterward fell into line, and now all to a man brand as morally unlawful craniotomy and every such operation. Here again the "anonymous writer" has not told the whole truth by not quoting Lehmkuhl in his last editions, where, taking the inspiration from Rome, as every true theologian does, he clearly condemns craniotomy.

What should we think of a writer who wishing to prove, in our days, that the "income-tax" is perfectly constitutional quotes an author who gave his views while this question was being discussed before the highest tribunal in our country? Would this be fair, especially if the decision given by the court is not at the same time made known? And what if the author whose views have been given as an argument had modified them and made them agree with the decision of the Supreme Court? This, and not less than this, is what the "anonymous writer" has done in regard to Lehmkuhl.

If both Rome and theologians condemn craniotomy, it is useless for Catholics to inquire whether any intrinsic reason may be found in its favor. Moreover, the question has been too extensively treated during these recent years to need now any additional explanation or comment. Indeed it must be asserted that apart from a certain sentimentalism, nothing has ever been brought forward to justify craniotomy from an ethical point of view. Craniotomy must be called to-day, as it was called many years ago by Archbishop Kenrick, of Baltimore, *immane facinus*, a monstrous crime. And to speak of "science" and "necessity" that we may connive at such crime is, to say the least, ridiculous. Science is advanced only by truth, and necessity, however great, cannot be admitted as an excuse for evil-doing. Is it not to be wondered at how inconsistent some of our friends are, who while they are perpetually slandering the Jesuits for that famous "The end justifies the means," wish to kill the child in order to save the mother? The Jesuits will never allow craniotomy for that very reason, because the end does not justify the means.

NOT A SAINTED BENJAMIN.

To the Editor of the Medical Record.

Dear Sir: The editorial reference in your issue of the 8th instant, to Mr. Ford's article on Benjamin Rush, would seem to call for some rejoinder from me as a eulogist of Dr. Rush; but without essaying the *rôle* of apologist, I beg to state that I have no doubt whatever that a man of his earnest convictions, enthusiasm, and energy did say and do a great many things that had better been left unsaid and undone, but in this he only shared the common weakness of mortal flesh, and although I know that *Tu quoque* is no argument, nevertheless I believe I have heard that the justly revered Father of his Country was himself a man with human failings like other great men from the times of the venerable Noah, the royal David, and the superlatively wise Solomon down to our own daily sinning selves. I am not proposing to erect a statue to any sainted Benjamin, but to a very great physician, who exalted medicine and dignified his profession, and to an undoubted patriot, who risked life and fortune for his country, which he left the better for his having lived.

GASTRO-INTESTINAL DISEASES OF CHILDREN, DUE TO MALASSIMILATION.[1]

BY N. J. PHENIX, M.D.,

ALVIN, TEX.

THIS subject, apparently "timeworn and threadbare," is fraught with interest to the general practitioner, and notwithstanding much has been said and written upon it, many physicians evince in their treatment a limited knowledge of the etiology of the gastro-intestinal diseases so common among children during the hot months. Even in the majority of text-books these diseases are discussed in the routine manner of "years ago." In reading our journals, however, it is gratifying to note the advancement in recent years, both in etiology and treatment, and the object of this paper is not so much for the presentation of new ideas or "new discoveries," as to formulate a correct review of the causes of "summer complaint," and present a rational treatment based upon a knowledge of the physiological and pathological conditions of the alimentary canal.

The two principal factors in the causation of infantile diarrhœas are atmospheric heat and improper feeding. With the advent of warm weather these diseases begin to increase in frequency and severity, reaching their maximum in July and August. In the rural districts gastro-intestinal disturbances are not so common nor so severe as in the squalid tenements of crowded cities. This fact leads to an investigation of influences besides atmospheric temperature. When filth, bad ventilation, and other unsanitary conditions abound with many children crowded together, we often find a veritable hot-bed of cholera infantum.

A temperature above 60° F., associated with unsanitary surroundings, favors the rapid multiplication of micro-organisms, which work destructive changes in food substances, and when taken into the alimentary canal develop those pathological fermentations and putrefactions which poison the blood and act as direct irritants to the mucous membrane and nerves, producing a variable train of symptoms, from malnutrition, diarrhœa (and sometimes constipation), to the severe forms of cholera infantum, characterized by fœtid discharges, vomiting, fever, collapse, convulsions, coma, or other nervous symptoms.

However much the various and numerous microbes whose development is favored by high temperature and bad hygiene may be considered the direct source of poison, it cannot be doubted that improper food furnishes pabulum whereby the pathogenetic organisms are more rapidly multiplied and distributed.

The direct action of the different kinds of food in the production of gastro-intestinal diseases probably has not received a due amount of attention from the majority of physicians.

The first time the child cries after it has been dressed, some ignorant old woman or nurse thrusts into its mouth a "sugar-tit," a "little cracker-water," sweetened catnip-tea, or some other starchy or saccharine substance for the digestion of which nature has made no preparation. The suckling babe, subsisting upon breast-milk alone, does not require the action of ptyaline. Hence the diastatic ferment is not developed in the submaxillary gland and pancreas until the infant is more than two and one-half months old. At birth the parotid gland alone contains ptyaline, and it is not found there in sufficient quantity for the conversion of starch into dextrine and maltose.[1] The amylopsin of the pancreas is not secreted in sufficient amount to admit of the free feeding of starchy food until the child has reached the age of about ten or twelve months.

Ignorant and silly mothers often feed their toothless babes *solid* food, both animal and vegetable, and cultivate an artificial craving for it, despite the fact that "nature declares in unmistakable terms that food requiring mastication is not appropriate to the digestive organs of a child that has no teeth."

Bottle feeding is a very fertile source of disease in young children, because it furnishes ample opportunity for bacterial contamination. The child nurses the same bottle from day to day, probably with only half cleansing, and the same rubber nipple, which sours and swarms with bacteria. This food, of course, soon ferments, and produces colic and green, acrid discharges, which excoriate, and the little sufferer, crying from the pain, has the sour nipple again thrust into its mouth. The stupefying carbonic acid produced by the fermentation may quiet it for a time, but the new supply soon adds to the already burning, seething mass, which passes through the alimentary canal, producing more colic and gastro-intestinal catarrh internally, and more excoriation externally.

Auerbach's ganglionic plexus, consisting of nerve-fibres and nerve-cells lying between the longitudinal and circular muscular coats from the œsophagus to the rectum, serves as an automatic motor centre, which supplies the intestines with normal peristaltic movements, so long as the circulation is kept at proper equilibrium and the blood contains the right proportion of O and CO_2.[2] This normal peristalsis is promoted by the healthy digestion of wholesome diet, but the presence of any irritating matter in the bowels, such as undigested, fermenting, and perhaps putrefying food, overstimulates these motor centres, produces hyperæmia, exaggerated peristalsis, catarrh, diarrhœa, vomiting, colic, and even active inflammation.

The intensity of the catarrh varies with the amount of bacterial and chemical poison operating. Whether the result is only a slight diarrhœa, or an intense inflammation, the cause operates in a similar manner.

In the form denominated cholera infantum we have unimpeachable evidence of the toxic effect of the micro-organisms previously mentioned. The vomiting, purging, griping, and cramping indicate extreme irritation of the nerves of the stomach and bowels. The hebetude, semi-coma, convulsions, and other nervous symptoms are indicative of irritation of the nerve-centres from the effects of blood poison or reflex action on the brain through the sympathetic nervous system.

In the treatment of gastro-intestinal diseases of young children our success will be in proportion to our strenuous regulation of hygiene and diet. The premises should be cool if possible, well ventilated, and scrupulously clean. The sick child's soiled napkins

and other clothing should not be allowed to remain in the house to putrefy and fill the atmosphere with poisonous germs. The excreta should be disinfected and the soiled clothing thoroughly boiled or destroyed by fire.

Frequent tepid baths will not only remove poisonous excretions from the patient's body, but serve as an excellent nerve and muscular tonic. The child's milk and other food should be carefully guarded against all possible sources of bacterial contamination. In fact, the proper nourishment of the child should be the chief concern of mother, physician, and nurse, from the time the umbilicus is tied until the period of dentition is past and perfect digestion and vigorous growth are established.

The mother's milk is nature's own food, prepared especially for the infant. It contains all the necessary nutritive principles, blended in such proportions as to promote health and vigorous growth. No animal's milk or prepared "infant's food" can take the place of the normal secretion of the breast of a healthy mother. The mother who weans her young babe to raise it upon the bottle, in order that she may enjoy the pleasure of high (?) society, commits a crime verging upon infanticide. Strong babes may thrive upon the bottle, but the weakly ones who have this severe vital test to undergo give employment to physicians, and contribute largely to the population of cemeteries. But, unfortunately the mother's health may be impaired and her milk unwholesome. If she is poorly nourished, and her alimentary canal contains an excess of fermenting, undigested hydrocarbons, and her whole dietary is deficient in the nutritive principles necessary to sustain her own body, how can she supply the proper nourishment for the child?

In order that her milk may be abundant and nutritious her general health should be good, her digestion normal, and her diet rich in tissue-building material, easily assimilated. Some women give an abundance of milk, but it is poor in quality. If the child cannot thrive upon its mother's milk, it should be weaned, or if circumstances will permit a wet-nurse may be employed, provided she is perfectly free from communicable diseases. A woman who nurses a child should have regular sleep, regular meals, and be perfectly exempt from worry and not overworked.

Sometimes the mother's milk is unfit for the infant on account of a systemic infection, from a lacerated womb with a purulent discharge, or some other similar cause. If such a condition be recognized, treat the woman.

When cow's milk is substituted for milk from the human breast, it should be given perfectly fresh and clean, from young, healthy cows that have been liberally fed and kept in clean, dry, warm, well-ventilated stables. The cow's udder and the milker's hands should be thoroughly washed and the vessels in which the milk is received should be rinsed in clean boiling water. No particles of dust, dirt, or foul air should come in contact with the milk. It should be carefully conveyed, without churning or shaking, into sterilized glass jars, and placed away where it will cool rapidly.

Unfortunately, few families obtain pure milk. Because of the myriads of bacteria that are swarming in low-grade milk, it becomes necessary to sterilize it. For home sterilizing the milk may be put into small, clean bottles. After the bottles are filled stop their mouths with cotton and place them in steamers or hot water (at 180° F. or more), and let them remain thirty or forty minutes.

Sterilized milk is less digestible than pure milk in its fresh, natural state.

When young infants are fed on cow's milk it should be diluted in the proportion of about one part of milk to two of water, gradually increasing the proportion of milk as the child grows older. After the milk has been diluted a little sweet cream and sugar of milk should be added. Care should be taken not to add too much sugar, one to two per cent. being quite a sufficient quantity. Condensed milk that is not over-sweetened is a quite satisfactory substitute for fresh milk. When properly prepared it is evaporated to one-fifth its original volume. The greater part of condensed milk on the market contains entirely too much sugar.

Starchy foods should not be fed to children under four or six months old. A little barley gruel may be admissible to dilute the milk if the child has diarrhœa, or a little oatmeal gruel if the child is constipated.

Some of the proprietary "infants' foods" are valuable preparations because their constituents nearly approach the composition of human milk. Others are worthless on account of the saccharine and starchy matter they contain.

If the child does not nurse the breast it should be supplied with about six bottles and as many rubber nipples. After nursing the bottle should be washed with boiling water, the nipple thoroughly cleansed with boric-acid solution, and both placed in the sun and allowed to remain until all the other bottles and nipples have been used in turn.

The proper regulation of the amount of food to be administered and the intervals between feeding are matters of great importance, too often overlooked. Dr. L. Emmett Holt[1] has demonstrated that the average capacity of a child's stomach at birth is about 1 ounce; at 2 weeks old, 1½ ounces; at 1 month, 2 ounces; at 3 months, 4½ ounces; at 7 months, 7 ounces; at 14 months, 9 ounces. Reference to this table will greatly aid in determining the proper amount of food to administer. If the stomach is repeatedly distended it becomes dilated and its capacity is increased beyond what is normal, while its digestive powers are proportionately diminished. If the food taken is not assimilated the body's demand for nourishment is not supplied, the sense of hunger is not appeased, the child cries for more and is not satisfied until the soporific effect of the carbonic acid produced by the fermenting food benumbs its sensibilities. Hence, overfeeding may produce malnutrition, and the child literally starves while its stomach is loaded with wholesome diet.

During the first day after birth the babe should nurse only two or three times. After that it should receive milk about every three hours during the day, and only once during the night. After it is six months old once every four hours is often enough for it to take nourishment.

In ordinary cases of infantile diarrhœa due to indigestion and bad hygiene a proper observance of the rules already lain down will usually be sufficient to effect a cure. Some cases, however, may require the aid of medicines. Use such remedies as promote digestion and destroy fermentations and putrefactions, and the diarrhœa will take care of itself. For the first purpose pepsin combined with muriatic acid stands, in my opinion, pre-eminently at the head of the list. Many physicians fail to get any benefit from pepsin because their doses are too small; many more fail because they ignore the physiological maxim that "Pepsin is inert except in the presence of an acid."[2]

Nux vomica and small doses of arsenic are valuable adjuncts, since they promote the secretion of gastric juice and serve as excellent nerve and muscular tonics. The following is a reliable mixture, which I have often used, and I can conscienciously say it has never yet disappointed me:

℞. Pepsin ..... ℥ ij.
Bismuth. sub. nit ..... ℥ ij.–iv.
Liq. potassii arsenit ..... ♏ xv.–xx.
Tr. nucis vom. ..... ♏ xxx.–xl.
Acidi muriatici dil ..... ♏ xxx.–xl.
Aquæ cinnamomi ..... q.s. ad ℥ iv.

M. Sig.: Teaspoonful three or four times a day after feeding for child six to twelve months old.

[1] See Annual of Universal Medical Sciences, 1891.
[2] See Landois's Physiology, p. 295.

The bismuth may be increased or diminished, according to the amount of diarrhœa or intestinal irritation present.

For fermentations and putrefactions I have found nothing better than sulphite of soda, two to four grains three or four times daily, midway between meals. It is especially valuable where there is green or excoriating diarrhœa.

Small doses of calomel ($\frac{1}{12}$ to $\frac{1}{4}$ gr.) repeated at intervals promote secretions, and serve as an intestinal antiseptic. A dose of castor-oil or syrup of rhubarb may be given when necessary to unload the bowels of irritating or poisonous matter.

The amount of nourishment should be diminished so as to come within the limits of the child's digestive capacity, and an abundance of pure sterilized water supplied.

I have often seen pure blackberry brandy control the diarrhœa, while at the same time it served as nourishment and stimulant.

If the above measures prove ineffective, and the diarrhœa is severe and persistent, a complete change in diet should be made.

There are at least two forms of fermentations: 1, acid, recognized by green, sour-smelling discharges, with flatus, colic, and excoriation; and 2, the putrefactive form, recognized by dark or brown fœtid discharges, with more or less vomiting and constitutional symptoms.

In the acid form avoid carbohydrates and feed on proteids. Germs of putrefaction thrive on an albuminous food. Withdraw the albuminoids, and starve out the germs. Milk containing both proteids and carbohydrates should not be given in any form of persistent intestinal fermentation. Meat broths and sweet cream may be safely given in either form.

In cholera infantum, during the first twenty-four to forty-eight hours, no food should be allowed. Give the child all the hot water it will take, preferably from a nursing-bottle. Copious enemas of hot water containing sulphite of soda or some other safe antiseptic should be slowly administered. In severe cases, especially when there is much vomiting, stomach washing by means of a Nelaton's catheter will be found valuable. At the beginning of treatment an evacuant in the form of calomel, rhubarb, or castor-oil is almost universally employed. Opiates should never be used until after thorough evacuation and cleansing of the bowels, and then only with extreme caution. If there is much fever, tepid sponge-baths will reduce the temperature and relieve the thirst.

If malaria be present, anointments of quinine should be freely used.

Every source of irritation should be removed. The physician should never fail to examine the gums, and when there is much tenderness and swelling I never hesitate to relieve the tension of the dental sac by scarification.

When the child nurses the breast the nipple should be carefully cleansed with boracic-acid solution. Enough germs may be retained on the nipple to start a new colony of bacteria in the child's stomach with each nursing.

After twenty-four to forty-eight hours' fasting, with thorough cleansing of the alimentary canal by means of stomach washing, irrigations of the colon, and evacuants, I cautiously begin the administration of small quantities of food, following with the bismuth, pepsin, and muriatic acid. Between the intervals of feeding some intestinal antiseptic should be given. Among the most popular should be mentioned bichloride of mercury (gr. $\frac{1}{100}$ every one or two hours).

Luff considers the biniodide of mercury a safer and more powerful antiseptic than the bichloride. He considers the milk ptomaine tyrotoxicon one of the chief factors in the causation of diarrhœa, and believes the biniodide of mercury renders the ptomaine insoluble and inert. Bichloride of mercury is powerless to precipitate the milk ptomaine. He prescribes the biniodide in the following form:

℞. Liq. hydrarg. perchlor. ..... ℥xij.
Pot. iodidi. ..... gr. ½
Chloral hydratis. ..... gr. j.
Aquæ. ..... ad f ℥ j.

This forms the teaspoonful which he gives every four hours to a child six months or under, every three hours to a child six to twelve months, and two teaspoonfuls to a child more than one year.

Salol and iodoform each have their ardent supporters. From recent reports I am inclined to believe that sulphocarbolate of zinc is a remedy of unquestionable value. It is non-irritating, sedative, antiseptic, and astringent, and may be given in doses of one-sixth grain to three or four grains, combined when necessary with bismuth and pepsin. My favorite antiseptic, as before stated, is sulphite of soda. To relieve the obstinate vomiting, I combine creosote or carbolic acid one-eighth drop to one-half drop with minute doses of cocaine in lime-water every twenty to sixty minutes. If physicians would devote more attention to the physiology of infantile digestion and direct their efforts toward the elimination and destruction of micro-organisms, instead of confining them with all their poisonous products within the child's digestive apparatus by means of opiates and astringents, it would not so often become necessary for an "all-wise Providence" to transport the little sufferer to a higher sphere,

Where aches and pains are never felt,
And microbes are no more.

A FATAL CASE OF EXCISION OF THE GASSERIAN GANGLION.

By ARPAD G. GERSTER, M.D.,

NEW YORK.

As the estimation of the true value of any new procedure can be arrived at only when everything regarding it, favorable and the contrary, is published, I deem it my duty to bring to public notice the following case:

H. B——, a robust, tall pianomaker, on whom Carnochan's operation had been done by myself in 1893 for an infra-orbital neuralgia then existing for seven years, having remained free from attacks for about a year, was operated on a second time by Dr. F. Kammerer, my colleague at the German Hospital, who excised the entire cicatrix and thus again procured relief to the patient in 1894. He was re-admitted with intense neuralgia on February 21, 1895, and excision of the Gasserian ganglion was determined upon. His general condition was good, and with the exception of a lagophthalmos and shallow corneal ulcer of the eye corresponding to the site of the former operations, all his organs were found to be in a normal state.

On February 25th, Hartley's operation was performed under good chloroform anæsthesia. The patient's skull was very large, its thickness and the normal processes and depressions all very strongly developed, a circumstance which is of practical importance, as the facility with which the operation can be performed is materially influenced by this. Where there is a small skull with slightly developed inequalities, the detachment of the dura is much easier, and the depth of the wound much less than was the case in the instance of this patient. The facts here indicated ought to be expressly mentioned in every published history, as they offer an important clew to the remarkable variations in the case of performing this operation observable in the experience of different surgeons. That this circumstance is of a real technical importance was further established by me in doing the operation on four cadavers,

three of which were women. Here the raising of the dura and the exposure of the ganglion were very easy in the women, as the inner surface of the temporal fossa was nearly level and the wound not very deep. In the fourth, a man's case, things were very much as we found them in the operation performed on the subject of this article.

The usual omega incision was made through the integument. The V-shaped gouge recommended by Hartley was found in my hands to be a very slow, ineffective, and treacherous tool. After the outer table was divided, the instrument easily penetrated the vitreous table, and in one place, an inch-long laceration of the dura was the result. I found that a well-sharpened carpenter's chisel of moderate width, held so inclined as to cut with one edge only, gave a much more rapid and satisfactory result in cutting the desired trench. Separation of the omega-shaped osteocutaneous flap required fully thirty-five minutes, and would have needed more time in a slow or timid operator. The middle meningeal artery remained intact, and no trouble was encountered from it. As the convolutions and sulci of this brain were very strongly developed, the inner surface of the temporal fossa was correspondingly uneven; and as the dura was intimately adherent, the stripping up necessary for the exposure of the Gasserian ganglion was not easy. An elevator had to be used here and there, and finally the foramen ovale was reached. Much cerebro-spinal fluid had escaped after the tearing of the dura, and hence the bottom of the cavity could be very well exposed by the aid of Hartley's lever.

In liberating the infra-maxillary branch of the nerve, suddenly profuse venous hemorrhage was encountered, which was very easily controlled by packing a small strip of iodoform gauze into the innermost angle of the cavity, but recurred each time when the packing was removed. Under these circumstances it was not deemed prudent to continue, wherefore the cavity was packed with iodoform gauze, the flap was returned to its normal position, and an external dressing was applied. The operation had lasted seventy minutes. Toward the end the pulse had fallen from 78 to 40 beats per minute, and became somewhat soft.

During the subsequent twenty-four hours the patient vomited twice, but otherwise felt well and was fully conscious and painless. Slept little in the night. On February 26th I found him somewhat drowsy, answering questions slowly but rationally. Pulse, 84; temperature, 100.2° F. Toward evening light delirium with some restlessness. After 10 P.M. he fell asleep and slept all night.

February 27th.—Patient more quiet. At 8 P.M., temperature, 100.6° F.; respiration, 22; pulse, 96.

February 28th, at 2.30 P.M., the patient was again chloroformed, the dressings, slightly soaked with blood and serum, were removed, the flap was raised, and the packing was extracted. The wound looked sweet and fresh as at the time of the first operation, the dura whitish except in the vicinity of the rent made with the gouge, where it was found blackish-blue, and apparently necrosed to the extent of the size of a five-cent piece. The exposed surface of the brain was pale and entirely normal-looking. There was no hemorrhage of any account this time, the second branch, greatly attenuated, but clearly identified by its entrance in the round foramen, was secured in a silk ligature, likewise the third branch. Then the dural sheath enveloping the roots of these nerves was split with the knife, the distal ends of the nerves were divided, and an attempt was made to evulse the ganglion. This did not succeed, as the nerves gave way, and the ganglion had to be removed in pieces with forceps and a small scalpel and scissors. The attenuation of the second branch might have been the consequence of the former operations done. In removing the ganglion some venous hemorrhage was again encountered from a spot behind the foramen ovale, but soon subsided. The necrosed portion of the dura was now excised, the flap was returned in its place, and having placed a slip of iodoform gauze in the posterior angle, the wound was sutured with catgut and dressed. At 8 P.M., temperature, 102° F.; pulse, 96. Patient slept fairly well.

March 1st.—Patient drowsy but rational, free from pain or headache, the temperature varying from 101.2 to 101.8° F.

March 2d.—Very restless; slept poorly and had to be restrained from getting up. Evening temperature, 102.2° F.

March 3d.—Quieter; pulse, 96; temperature, 101.8° F. in the evening.

March 4th and March 5th.—Gradual rise of pulse to 128, and of temperature to 102.6° F., with temporary remissions.

March 6th, 12 P.M.—Temperature, 103.5°F.; pulse, 80; delirium; pulse at times irregular, intermittent, and becoming slow down to 50.

March 7th.—Temperature, 102° F.; pulse as yesterday. Patient restless, at times delirious, but spoken to perfectly clear and rational, free from pain. The dressings were removed, and a clean, sweet, and dry wound was found, from the bottom of which, on removal of the deep packings, about a drachm of pale, entirely clear serum escaped. The brain was found still considerably retracted, its surface pale and pulsating. As we suspected the presence of an abscess several punctures were made through the temporal lobe without yielding anything. The wound was closed, and an encephalitis due to mechanical injury of the brain corresponding to the site of the operation was assumed as the only rational explanation of the patient's condition. There was no sign of paralysis or irritation at any time. The temperature remained at about 103° F., pulse varying above and below 50, and patient remained conscious to within fifteen minutes of his death, which occurred on March 8th. The lungs and kidneys had never shown any signs of disorder.

Autopsy of the skull—general autopsy not being permitted—revealed no signs of meningitis. In the basal portion of the temporo-sphenoidal lobe, corresponding to the deepest part of the wound-cavity, and overlying the greater wing of the sphenoid, a focus of softening of the size of an English walnut, involving the cortex, and containing débris of brain-matter of the color of crushed strawberries, was found. The definition of this focus from the healthy brain was very sharp.

The conclusions to be drawn from this history are: 1. That in certain individuals, on account of local peculiarities of the skull, Hartley's operation may be a technically very difficult undertaking. Hemorrhage may not only be an impediment to safe operating (Keen), but will also be dangerous, producing acute anæmia (shock). 2. Bruising of the brain-matter—be the pulpification due either to direct mechanical influences or to local hemorrhage, or both, is a danger not to be slighted.

The Jury System and Medical Experts.—Two years ago a patient was sent to Bloomingdale with the diagnosis of paresis. He was taken out and a commission appointed to determine his sanity. The medical experts said he was insane, but the jury voted unanimously that he was not. He was discharged. He lately died of paresis. This is only one of many cases in which juries have made mistakes, but it is only the disagreements and mistakes of experts which are exploited in the papers.

Should a Priest Ride a Bicycle is a question that is said to be under consideration by the Roman Catholic authorities. It has been suggested that such a form of exercise is derogatory to priestly dignity.

THE USE OF TORSION INSTEAD OF LIGATURES.[1]

By JOHN F. ERDMANN, M.D.,

NEW YORK.

PROFESSOR OF PRACTICAL ANATOMY, BELLEVUE HOSPITAL MEDICAL COLLEGE; LECTURER ON DISEASES OF THE RECTUM, BELLEVUE HOSPITAL MEDICAL COLLEGE, SUMMER SESSION; VISITING SURGEON TO THE WORKHOUSE AND ALMSHOUSE HOSPITALS; VISITING PHYSICIAN TO CITY HOSPITAL; CHIEF OF THE SURGICAL CLINIC ST. VINCENT'S, OUT-PATIENT DEPARTMENT, ETC.

MR. CHAIRMAN AND GENTLEMEN: At the present day our object in all operative procedures is to obtain primary union, and to obtain this result we believe that the less foreign matter introduced between the flaps the greater will be the chances of such union taking place. Knowing the difficulties we meet in the sterilization of the organic ligatures so commonly used at present, and also the almost impossible feat of keeping these ligatures sterile or antiseptic during an operation, especially in private practice, I resolved to try torsion as a means of checking hemorrhage from the divided vessels. By its use we dispose of the ligatures that act as foreign bodies, and which are very likely to be a source of irritation and also a possible means of infection, either by not being sterile primarily or by becoming infected, as a result of exposure and contact during the operation, with hands and materials not sterile nor absolutely antiseptic, and further, we dispose of a possible means of hemorrhage due to an imperfectly tied knot or slipping of the knot due to the condition of the ligature as occasionally observed in the use of catgut. As a result of disposing of these undesirable features primary union is much more apt to attend our efforts. Another consideration, but of minor importance, is the time occupied in doing torsion as compared to ligation. Torsion requires but the turning of the forceps, in the unlimited method, four to eight times, in the limited it requires the proximal fixation by means of a forceps or the finger and thumb, and then giving the distal forceps four to eight turns, and finally, the releasing of the forceps in either of these methods; while in ligation the ligatures are cut, then passed by an assistant, provided we are fortunate enough to have one, then tied, then the free ends cut beyond the knot, and finally releasing the forceps, thus causing an unnecessary amount of handling of material and a corresponding increase of danger of infection. It is but proper to state that we cannot apply torsion to all vessels, nor do we advocate it; occasionally a vessel is grasped and all attempts at torsion fail, the vessel bleeding as a result of the tearing of the walls owing to disease. Two such instances occurred in my work during the last eighteen months, one being in a radical cure for hernia, and the other in a case of dissection of the axilla for secondary growths following malignant disease of the mammary gland. In these cases the use of the ligature was followed by the same result until I included some of the surrounding tissues in the ligature to prevent its cutting through the coats of the vessel.

The possibility of hæmatoma, or secondary hemorrhage, occurring as a result of this means of checking hemorrhage is very slight, in fact, I would say much less when properly done than in ligation. This occurred once in my cases (a case of radical cure for hernia) out of about one hundred and five operations, and in this case I have always attributed the cause to the patient's displacing the dressings in the first twenty-four hours; but even here it was not sufficient to require the opening of the wound to check the bleeding, and had drainage been used it would have been considered as simply an excessive oozing. Owing to the fact that primary union is more apt to follow in cases where this method has been used, for reasons previously stated, secondary hemorrhage naturally will occur with much less frequency, and as early adhesion of flaps acts as a mechanical agency in preventing hemorrhage recurring, it is my custom in all cases where possible to close my wound without drain and seal it with plain flexible collodion. The absence of drainage and ligatures allows of better apposition and earlier adhesion than in cases where they have been used.

Torsion is either limited or unlimited; by the former some means is employed, usually a forceps or the thumb and finger grasping the cleared vessel, to prevent the twisting of the vessel beyond a certain point; while in the unlimited variety twisting is only limited in the length of the vessel-walls by the number of turns given to the forceps grasping the end of the vessel, or by the first large branch given off above the bleeding point, and also by the surrounding tissues.

Limited torsion is done by grasping the bleeding point with an ordinary artery clamp, then drawing the artery out and clearing it for a short distance of all surrounding tissues, then grasping the proximal end of the cleared portion between another pair of forceps, preferably narrow bladed, or between the thumb and a finger for a point of limitation to the twisting, and then giving the distal forceps four to eight turns.

Unlimited torsion consists simply of twisting the vessel with the forceps at the bleeding orifice four to eight times. My custom has been to grasp the bleeding point, then grasp the proximal portion without especial care to exclude all of the surrounding tissue in small vessels, and to clear carefully in the larger ones, then giving the forceps four to six turns. Care should be taken to grasp the vessel so as to occlude the entire lumen, otherwise a portion of the wall only is grasped, and imperfect torsion is done, or a portion of the wall is torn off, and in either instance the bleeding continues and the desired results are not obtained.

As a result of torsion on vessels[1] the inner and middle coats rupture, and an incurvation and retraction takes place in them resembling a valve-like or nipple-shaped occlusion; this incurvation takes place in the opposite direction of the blood-current and favors the coagulation of the blood: whereas[2] in ligation there is no incurvation, but the inner and middle coats rupture and invert slightly and resemble a V-shaped mass. The ends beyond the point of rupture of the walls are absorbed or become contracted, with less danger to the patient than the ends in cases of ligation, owing to the presence of the foreign and possibly infected material used in the latter method.

In conclusion, I regret to say I can present you with no cases of my own of torsion in vessels of the size of the brachial and femoral in man, but give you some of the results of others on large vessels.

Thomas Bryant[3] says that "for fifteen years I've used torsion, the femoral being the largest, never having a mishap; and think it the most physiological method of checking hemorrhage."

John H. Dill, F.R.C.S.,[4] reports seventy cases with no mishaps, and in a list of thirty cases, we find reported torsion of the femoral five times, popliteal and brachial each twice, and the axillary once, all being successful.

M. McCormac,[5] of St. Thomas's Hospital, reports the use of torsion to the exclusion of any other method, among the cases being many of the femoral at the hip, with but one case of secondary hemorrhage, and that was due to acute pyæmia in a gunshot of the hip, in which the result would have been the same in ligation.

Warren[6] quotes Kocher as follows: "Torsion has a great advantage of forcing a rapid coagulation, and has also its own especial advantage of producing a much more intimate union between the vessel-walls and the thrombus."

[1] Read before the Surgical Section of the Academy of Medicine, May 12, 1895.

Finally, I present you with the following list of operations occurring recently to show that I've used no selected cases nor regions. The average age was forty-nine years, the oldest was seventy-seven years of age, and the youngest eight and one-half months; 31 radical cures for hernias, 4 being ventral and umbilical; 2 explorations of the cranial cavity; 8 abdominal sections, including hysterectomies (ligatures being used in the broad ligaments), ventro-fixations, enterectomy, and appendix cases, colotomy, and a retro-peritoneal growth; 9 genito-urinary, including castrations, transplantation of urethra after amputation of the penis and perineal sections; 3 gynecological cases, of minor importance; 8 malignant growths of the breast with axillary dissections —6 in the female, 2 in the male; 3 operations upon the upper extremities; 5 operations upon the trunk and lower extremities, the latter including two amputations in which I did not trust to torsion of the femoral and popliteal, owing to diseased vessels, and two removals of portions of the rectum; 6 cases on the head and neck, in addition to the cranial explorations: 30 incidental and minor cases.

149 West Forty-fourth Street.

CHANCRES AND CHANCROIDS IN THE URETHRA.

By C. B. LONGENECKER, M.D.,

PHILADELPHIA, PA.

Chancres and chancroids in the urethra are, in all probability, often overlooked; and, if found, their treatment becomes a matter of considerable difficulty, especially to the general practitioner—so much so, in fact, that these cases are often handed over at once to the specialist, while the general practitioner congratulates himself as being well rid of a troublesome case. But, if a little care should be taken by him to investigate any suspicious discharge from the urethra that does not exactly resemble a gonorrhœa, and if, when found, a little care as to treatment of same be given, results will be obtained that will be a credit to him and to his patient; or, if neglected, may go from bad to worse, until finally the case passes from his hands to the specialist, and the result is not only the loss of the patient, but loss of confidence in the ability of the general practitioner by the patient. I therefore wish to make a contribution to the subject of chancroids in the urethra, and their treatment, prompted in so doing by a case that fell into my hands (being declared as gonorrhœa by another doctor who first saw the case), and by an article by Dr. Clark in *The Boston Medical and Surgical Journal* of December 20, 1894. This I wish to do more especially because Dr. Clark's methods of treatment are almost identical with those used by me, and the results are likewise all that can be desired.

I have only one case to report, it is true, but Dr. Clark reports two others; and probably still other cases could be found to bear out the efficiency of this form of treatment of a disease which, when located in the urethra, is most difficult to handle.

In the case which I report, the first lesion was a chancre, which was followed, when nearly well, by a well-developed chancroid higher up in the urethra, and it was this chancroid that gave most of the trouble.

A young man called on me in January, 1894, and wished me to examine and treat a discharge from the urethra which, he had been informed, was a gonorrhœa. He had already had two or three attacks of gonorrhœa, the last attacks of which, he said, still gave him trouble. Some months ago had a bubo, which was opened, but which still continued to discharge. He was of the opinion that his present discharge was gonorrhœal, as he had been exposed two weeks, and again one week, before the discharge began. Discharge had been present one week before he presented himself.

On examination a sero-purulent discharge was found, coming from the urethra. Just within the meatus, and on one side, he complained of a tender spot. This led to an examination of the urethra, when a chancre was discovered, just within the meatus and extending into the urethra about three-eighths of an inch, no part of it being visible externally. This was cauterized with pure nitric acid after applying four per cent. cocaine solution to the part. The acid was quickly neutralized with solution of sodium bicarb. The urethra was then plugged with a cotton tampon smeared with aristol ointment, twenty-five per cent. strength. These tampons were formed by twisting a pledget of cotton on to a screw-thread applicator, smeared with ointment, and inserted in the urethra while still on the applicator; when in position the applicator was unscrewed, leaving the cotton in position, leaving one end protruding from the urethra, while the inner end was carried well beyond the ulcer. This tampon was withdrawn by the fingers before urination and replaced with a fresh one after.

That the lesion was a true chancre was very definitely proven by all the secondary symptoms coming on about six weeks after the appearance of the primary sore—old bubo increased in size and discharged freely; sore throat with mucous patches; hair coming out; painful nodes about scalp; abundant rash; and finally, disappearance of all symptoms under specific treatment in a very brief time.

The ulcer which followed cauterization of the chancre was doing nicely under aristol tampons, and was nearly well, when the patient's desires got the upper hand of him and he again exposed himself to contamination, with the result that in a few days a chancroid spread along the urethra, beyond the original lesion. This one gave more trouble than the first, as it was harder to treat, had a tendency to spread rapidly, and was much more painful.

This chancroid was cauterized with arg. nit. solution (about one-half strength of saturated solution), as it was a question whether it would be advisable to go so far into the urethra (about three-quarters of an inch from meatus to further edge of ulcer) with an agent so strong as nitric acid. But the result demonstrated, probably, that nitric acid would be preferable, as a tremendous œdema followed arg. nit. solution, necessitating the use of a catheter for removing the urine for several days, as the urethra was entirely closed; and this followed the greatest care in the application of the solution, and the use of salt solution afterward to neutralize the arg. nit. application. If another case comes my way nitric acid will probably be used, as the ulcer seems to heal quicker and cause less disturbance, besides being rather more radical treatment.

In regard to a catheter, I may say that a woven catheter (a short length cut off), of small size, was first used; but the insertion of this caused great pain on account of the rough end. Casting about as to what next to try, for he had to have something to carry with him, a glass tube was decided on, and it was found to be most satisfactory, as it could be inserted without pain, and was easily kept clean. A glass tube of No. 14 French, about three inches long, with ends rounded in the flame of a spirit lamp, constituted the catheter, and it is one that anyone can make for himself. For lubricant, boro-glyceride, twenty-five per cent.—itself an antiseptic of no mean degree—was used. This catheter was used until the œdema had subsided to a great extent, when a size much larger was substituted for it; this served to distend the urethra each time it was used, and its use was continued until the ulcer was healed, with the result that it, with the cotton tampon, left the urethra about its normal size. The cotton tampon was likewise continued until healing was complete, which, for the second ulcer, was rather long delayed. But it was helped along by the local application of tr. iodi. Eventually a complete recovery was the result.

I may add that I desire nothing better for examining

this portion of the urethra than an ear speculum or a dressing forceps, both of which can be used to advantage.

For ease in applying the speculum an obturator was made of glass tubing of a size sufficiently large to fill the small end of the speculum; the end was rounded and closed in an alcohol flame; a short distance back an angle was formed which acted as a stop against the side of the speculum, to prevent the obturator from being pushed too far through.

The method of examining is similar to that used for the deep urethra: the speculum and obturator are inserted together to the proper depth, going beyond the ulcer. The obturator is then withdrawn. With a good light thrown into the speculum it is slowly withdrawn, and the whole surface of the ulcer comes into view, when applications can be made as desired, and without guesswork.

The final healing of this ulcer under aristol ointment, with a touch of tr. iodi every day or two, was all that could be desired, and nothing more stimulating was demanded in this case.

This young man carried his "surgical kit," consisting of aristol ointment, absorbent cotton, applicator, catheter, and boro-glyceride, all in a little package in his vest-pocket, and he experienced no trouble in using them correctly; he always used them, as his catheter was quite necessary to his well-being, and to have forgotten or mislaid it would have subjected him to considerable discomfort.

In conclusion, the attention of the general practitioner is directed to the following points: 1. Examination of anterior urethra when a sero-purulent discharge or pain is present. Examine with speculum and in a good light. 2. If lesion is found, a prompt and complete cauterization of it with nitric acid. 3. The distention of the urethra with a tampon of cotton or other suitable material, and an ointment, until healing is concluded. 4. The use of a glass or other easily-cleaned short catheter for urination. 5. The use of the speculum and a good light for subsequent topical medication, and inspection of healing process.

3501 Hamilton Street.

Anæsthetics: the Collective Investigation.—Professor Gurlt, the secretary of the Congress of German Surgeons, has made a report on the above subject. The collective investigation has now been going on for five years. This year 52,677 new cases were reported, of which 31,803 were chloroform narcosis with 23 deaths, and 15,712 were ether narcosis with 5 deaths. In 2,148 cases narcosis was produced by a mixture of chloroform and ether, in 1,554 by the so called Billroth mixture, in 1,425 by ethyl bromide, and in 34 by penthal. The use of ether has much increased. The mortality from chloroform seems to be much greater than that from ether; but very often grave disorders of the respiratory organs, such as pneumonia and bronchitis, result from the inhalation of ether, and death from those complications ought to be regarded as equivalent to death under anæsthetics. Ether was especially harmful after laparotomy. Dr. Schleich (Berlin) explained his theory of the action of anæsthetics. According to him, they are more dangerous the more their boiling-points differ from the temperature of the body. He has devised an anæsthetic mixture (chloroform and petroleum ether) whose boiling-point is the same as the temperature of the body, and states that he has obtained excellent results, all the disagreeable symptoms (vomiting, etc.) being absent. Dr. Rosenberg (Berlin) recommended that the mucous membrane of the nose should be brushed with a solution of cocaine before the commencement of the narcosis. Dr. Rehn (Frankfort) gave a warning against the use of chloroform near a gas-light, as ethylene chloride is formed.

Progress of Medical Science.

A New Method for Anchoring the Kidney. — Dr. Reed calls attention to the following anatomic landmarks in anchoring the kidney. Clinical experience teaches that movable and floating kidneys occur more frequently on the right side than on the left. In this connection it is well to remember that the right kidney, when in its normal position, is usually located a little lower than its fellow, and, on the average, measures about four inches in length. The left kidney is usually longer and narrower than the right kidney. The upper margin of the right kidney, when in its normal position, is on a level with the twelfth dorsal vertebra. This throws its margin slightly above the upper border of the twelfth rib, which is an important point to remember in the operation the author describes further on. The left kidney being located a little higher than the right, its upper margin not infrequently is on a level with the lower border of the eleventh rib, and sometimes even reaches a point slightly higher. The right kidney is usually about two and a half inches in width, while the left kidney seldom exceeds two inches, but makes up for its reduction in width by increase in length. They are each about one inch in thickness, which is also an important factor in considering the question of anchoring. By keeping these anatomic memoranda in view, the operator will be able to comprehend the mechanical conditions that are present, and which he must meet in anchoring a floating or movable kidney in its normal position. Reed's operation consists in making the ordinary perpendicular abdominal incision over the median line of the kidney. As a rule, it need not exceed two and a half to three inches in length, depending largely on the thickness of the abdominal walls. Having made the incision sufficiently large to get the fingers in and bring the kidney to its normal place, he then uses a long needle, varying from five to seven inches in length. Two of these needles are threaded with aseptic silkworm gut or aseptic silk, using but one ligature, armed with one of these long needles at each end. Having placed the kidney in its normal position (and in the case of a floating kidney having scarified the peritoneum so as to favor adhesions), he inserts his first needle through the upper and inner part of the cortical substance of the kidney, directly through the muscles of the back, coming out between the eleventh and twelfth ribs. The second needle, which is on the other end of the ligature, is also passed through in a similar manner, about an inch from its fellow, through the upper and outer cortical substance of the kidney. These ligatures are tied on the integument. If necessary, another suture is inserted through the outer margin of the kidney, the first needle of the second suture being passed about an inch below the last needle of the first suture, and the second needle of the second suture about an inch below the first needle of the second suture, through the cortical substance of the outer portion of the kidney. By anchoring the kidney in this manner, the entire operation can be performed in not to exceed fifteen minutes, unless there are some troublesome complications to contend with. In tying the sutures, care should be taken to draw them sufficiently tight to not only hold the kidney in place, but to produce sufficient irritation to excite inflammatory adhesions, which are intended to hold the kidney in place, and which are essential to make the operation a permanent success. It is also necessary to be guarded against tying the sutures so tight as to cut through the peritoneum and the substance of the kidney. Either of these conditions, however, can be avoided by care on the part of the operator. After properly tying the sutures, the abdominal wound is closed in the ordinary manner. The anchor is allowed to remain from ten

days to two weeks. At the end of this time adhesions are formed sufficiently strong to hold the kidney in place when the anchor is removed, and in two weeks more the patient will be able to leave the hospital. The advantages claimed for this operation are simplicity, rapidity, and efficiency. The operation is practically bloodless. There is no danger of injuring the abdominal viscera. It is easily performed, and the results so far are certainly very satisfactory, as illustrated by the case with which the author concludes his paper. —*The Therapeutic Gazette.*

Cerebral Amyotaxy.—Dr. Rossolimo applies this term to the form of hyperkinesis presented in the following case (*The British Medical Journal*): At the time of reception into the clinic in October, 1893, the patient, a clerk aged thirty-three, exhibited continuous spasticity and jerking movements in his right upper limb. The arm was a little abducted, the elbow flexed, and the fingers were bent into the palm, or variously flexed and extended as in athetosis. At times the contractions extended to the muscles of the neck and trunk. The hyperkinesis was aggravated by direct efforts to restrain the movements; by slight emotional disturbances; by diversion of the attention—for example, to a mathematical problem; as well as by strychnine, Indian hemp, and the early stage of choloroform narcosis. During sleep both tonic and clonic spasms disappeared. They were lessened by strong emotion, such as anger; by fixing the attention on little digital exercises that the patient had devised successfully for his relief; they were also diminished by morphine, chloral, atropine, and phenacetin. Galvanization of the head and neck gave unfavorable results, but faradization of the limb quickly relaxed the tense muscles. The whole musculature of this limb was hypertrophied. Voluntary movements of the right hand were much facilitated by simultaneously executing a corresponding movement with the left hand. In the muscles of the other limbs, and of the trunk and face, were frequently recurring clonic contractions, involving smaller or larger fasciculi or whole muscles, and producing involuntary movements, specially noticeable in the fingers of the left hand. The patient stammered badly; attempts to speak excited disordered action in the respiratory and laryngeal muscles, as well as those of the tongue and face. This speech-trouble dated from childhood; the other motor anomalies began in 1891, affecting first the digits of the right hand in a manner resembling writer's cramp, and gradually spreading therefrom. Myotatic irritability not excessive. Electrical reactions normal. Muscular sense and cutaneous sensibility unaffected. The only abnormalities in connection with the eyes were slight insufficiency of the interni, and diplopia. The latter did not appear until December, 1893, and was more pronounced whenever the movements in the right arm were most extensive. The author discusses reasons why this case cannot be classed as mogigraphia, athetosis, or under any other established nosological denomination. Taking into account the patient's neurotic heredity (mother and two sisters hysterical, brother hypochondriacal) and stigmata of degeneracy (obsessions, etc.), he thinks that the cerebral amyotaxy must be regarded as the motor symptom of degenerate brain structure, in the same way as the imperative ideas are the psychical symptom.

Non-operative Treatment of Congenital Dislocations of the Hip.—Schede has since 1880 treated these cases by orthopædic methods, which have given him excellent results. Upon the ground of his experiences he holds that the congenital dislocation of the hip-joint is by no means the incurable condition which it has been supposed to be, and that under certain circumstances it cannot only be greatly improved, but brought to a complete anatomical cure. His method rests upon the fact that in the vast majority of children with congenital hip dislocation, in whom no secondary changes have been caused by walking, a simple traction upon the leg and a slight abduction suffice to place the head in the acetabulum, and that, further, a moderate lateral pressure upon the greater trochanter is only necessary to retain the head of the bone in this position. After the child has begun to walk, the prognosis is less favorable. By the end of the second year, certainly in the third, the changes have become so marked that simple manual extension no longer suffices to reduce the deformity. But in such cases the employment of continuous extension by means of weights for a few weeks or months so restores the positions that, with abduction and pressure over the trochanter, the head of the bone may be made to go back into its place and remain so firmly that pressure upon the sole of the foot no longer causes it to ride out. In order to combine the lateral pressure over the trochanter with extension, Schede has had constructed splint apparatus, which differs from the common splint of Taylor in that the abduction-hinge is transferred from its position above the flexion-hinge for the hip-joint at the upper border of the pelvic band, and placed a little below the flexion-hinge. The screw which regulates the angle of abduction does not now work against the pelvic girt, but against the upper part of the cuirasse, which extends up to the tip of the trochanter. This itself is changed into a two-armed lever, the hypomochlion of which is the abduction-hinge. The more the abduction, the stronger the pressure upon the upper border of the thigh-piece against the trochanter major. The counter-pressure comes upon the sound side of the pelvis through the pelvic girt. In the application of the apparatus, the following cautions are laid down: 1. In putting on the shoes no pressure should be exerted upon the hip-joint. The pressure should be counterbalanced by extension upon the leg. 2. The abduction-screw permanently fixes the position which the physician wishes. It should be so arranged that it cannot be accidentally turned. 3. When the shoe has been put on and the upper and lower leg-pieces fastened, one person takes hold of the leg and splint and makes strong extension in the direction of abduction, while another fastens the pelvic girt.

This splint should be worn till a cure is effected. As repairs have to be made in such apparatuses, a duplicate should always be on hand. The child should not take a single step without the apparatus after the treatment is once begun. At night moderate extension of four or five pounds is kept up by the use of the air-pillow leg-girt. The apparatus should be gone over and readjusted at least every six or eight weeks.

Schede presented before the Congress a number of patients treated after his method. The first was a fifteen-year-old girl, who, when she was eleven months of age, suffered an unfavorable prognosis from Martini and R. von Volkmann. For three months she was treated by Schede in moderate extension. The splint was then applied, and at the end of a year she was completely cured. For the sake of safety she wore for six months a short abducting splint. Since then she had had no treatment. The cure is absolute and complete. The function of the joint is normal, and nothing abnormal can be discovered about the joint. He presented also a five-and-a-half-year-old girl, which he had begun to treat three years before; and a twelve-year-old boy upon whom he began treatment at the age of six. In these the treatment is not completed, but a good result is certain. They walked without splints without limp. The head is in the position of abduction, and when the leg is in normal position the head is entirely in place, and the trochanter is at the proper height. A slight dislocation can be detected when the leg is strongly ad ducted, and at the same time the thigh is pulled upward. Schede also reports four children which came under treatment at the age of from five months to eighteen months. The duration of treatment was one

to four years. Eleven others, among which are the two cases presented, are nearly cured, and excellent results will be obtained in all. Treatment was begun at ages ranging from seventeen months to four years. Only the boy presented was six years of age. They wore the splints from eighteen months to six years of age. Great improvement has been secured in eleven more cases, in which treatment was begun ranging from two to five years of age. In all of these a considerable period of treatment by extension had to be employed, though the head in all cases was brought into place and held there by the splint. Among four cases somewhat older, eight to ten years of age, three patients after wearing the apparatus over a year were greatly improved, inasmuch as the leg was lengthened, and the gait much improved. They still wear the splint. The fourth case was made to discontinue the use of the apparatus because the parent lost patience with it. In contrast to these, eight cases are reported in which the results are less satisfactory. In three the parents did not show the necessary interest, and the treatment was eventually abandoned. In six children, ranging from three to seven years of age, the secondary changes were so great that a reduction of the dislocation could not be accomplished. Orthopædic treatment was not tried in these cases. Two of the cases were operated upon and good results obtained. In four other cases of children, from two to three years of age, the treatment was carefully carried out for some years, but no satisfactory result was reached. Two of these were cured by operation. Schede has thus reported his experience with twenty-nine cases—four cured, eleven almost cured, and fourteen but slightly improved, of which the majority will have a good result. There are eight cases without result, and eight which were lost sight of, six of which were not adapted to the treatment. Besides the fifty-one single cases, Schede has had thirty double dislocations. He regards an early diagnosis of the greatest importance, as having a bearing of much moment upon the treatment and prognosis. —*Annals of Surgery.*

The Acute Infective Diseases and Abortion.—Dr. Klautsch says that pregnancy may be brought to an end either by the death of the fœtus or, less frequently, by premature uterine contractions. The fœtus may die owing to (1) deficiency of oxygen; (2) alteration in temperature; or (3) direct transmission of the infection. These conditions may be combined. The inconstancy of the transmission of the infection the author would explain by the circumstance that it can only occur when the normal connection between the maternal and fœtal circulation is disturbed. Premature pains may be caused by (1) increased body temperature; (2) altered blood; (3) changes in the uterine mucous membrane, as in endometritis exanthematica; or (4) toxins present in the blood. If the deficiency in oxygen occurs rapidly, the fœtus dies; if more gradually, pains are induced. In typhoid fever abortion occurs in more than half the cases, and the fœtus is mostly born dead, the death being most often due to the transmitted infection. Cholera is not transmitted to the fœtus, the death being here due to the altered blood, to an endometritis, to a diseased fœtal placenta, and to temperature variations. In measles the fœtus rarely dies. In severe malaria the fœtus is more often born alive, but soon dies of malarial cachexia. In pneumonia the death of the fœtus is not uncommon, and is due to asphyxia. Variola frequently kills the fœtus, yet many are born alive. As regards the pains, the fœtus may be expelled in variola even during the suppurative stage; in malaria after the paroxysm; in erysipelas most often when the eruption appears; in cholera during the transition stage; in influenza soon after the onset of the febrile symptoms; and in pneumonia on the third or fourth day. In typhoid fever the abortion may be accompanied by much hemorrhage, or strong contractions and little hemorrhage. In cholera the hemorrhage is profuse and the contractions violent. The fœtus is mostly much more threatened by the altered temperature, disturbed circulation, and pathological changes in the endometrium, than by the transmission of the infection.—*Muenchener medicinische Wochenschrift.*

Leucorrhœa in the Unmarried.—According to Dr. Slocum (Philadelphia Polyclinic), in the treatment of leucorrhœa in young unmarried women instances frequently occur in which the usual practice of making an examination to ascertain the condition of the pelvic viscera is so obnoxious to the patient, or is so firmly opposed, that the physician is forced to abandon it and have recourse to medicine. In such cases Dr. Slocum has learned to depend upon the specific action which cantharides appears to exercise upon the cells constituting the genital as well as the urinary system. It is probably by direct stimulation of the cell just to the point of successful resistance that the benefit is secured, as the dose is very small. Strangury, or other unpleasant symptom, has not been produced. The action of the drug has been so uniformly satisfactory that when it fails such result forms a strong basis for suspecting the presence of something more than simple hyperæmia or mild inflammation. Lessening of the discharge is sometimes noted within five days, but in several cases of profuse discharge of four years' and longer duration, the treatment was not successful until after a month's persistent use. The formula which has seemed the best contains the tincture ferric chloride and dilute phosphoric acid. These, though probably modifying the action of the cantharides, are only adjuvants. Following is the usual form of administration:

Tincture cantharides	♏ xcvj.
Tincture ferric chlorid	♏ clx.
Diluted phosphoric acid	♏ clx.
Sirup lemon	fl. ℥ ij.
Water sufficient to make	fl. ℥ iv.

M. S.: One teaspoonful, in water, after meals.

Onychophagia a Sign of Degeneration.—As the result of an inquiry carried out in several schools, for both sexes, Dr. Bréillon is confirmed in the opinion which he has already expressed, namely, that onychophagia, and habits of a similar order, are generally connected with degeneration. The frequency of onychophagia is very variable in different centres. In some schools not more than two or three children out of ten are addicted to nail-biting, but in others, and especially in the city of Paris, the proportion of onychophagians is often very considerable, amounting in the aggregate to upward of a third of the total number of pupils that came under observation. A careful examination almost always brings to light the stigmata of degeneration. The children who indulge in the practice are commonly more puny than the others; and they frequently present cranial deformities, irregular teeth, abnormally placed and shaped ears, etc. It has been noted by many teachers that the subjects of onychophagia exhibit a well-marked antipathy toward physical exercises, and more especially toward games involving sustained efforts. They write badly, and in general are remarkably deficient as regards manual dexterity. Perseverance is never observable among them, and for the most part they are unmanageable. In a word, when compared with other children of the same age they invariably manifest inferiority in some shape or form. All teachers agree that the pedagogical methods usually employed are quite unable to effect a cure. In the majority of cases this can only be obtained by the use of hypnotic suggestions. Ordinary suggestion, in the waking state, is only occasionally successful. The habit of nail-biting sometimes persists to an advanced age. In our own practice we have successively treated an old man seventy-two years of age, and a lady fifty-six years of age, who from earliest infancy had been incessantly the victims of onychophagia.—*Annales de Psychiatrie.*

Reviews and Notices.

Antitoxin Therapeutics of Diphtheria, According to the Observations Made in the Emperor and Empress Frederick Children's Hospital in Berlin. By Professor Dr. Adolf Baginsky. Die Serumtherapie der Diphtherie nach den Beobachtungen in Kaiser- und Kaiserin-Friedrich Kinderkrankenhaus in Berlin. Pp. 330. Berlin, 1895.

In his brief preface the author states that the material on which his book is based consists of all the cases treated from March 15, 1894, to March 15, 1895, exclusive of the months of August and September, during which no antitoxin could be obtained. During the ten months of persistent administration of the remedy he came to two conclusions: First, that bad cases which offered a bad prognosis according to previous experience would steadily improve and get well; and second, that when the administration of antitoxin had to be interrupted the former mortality returned at once.

The final conclusions of the book, which consists of two about equal parts—1, A general review of the symptomatology and pathology, and the therapeutics of diphtheria; and 2, a tabulation of 525 cases treated with antitoxin—are as follows:

1. The Loeffler bacillus is the cause ("Erreger," inventive) of the malady which is characterized as "diphtheria" by its clinical course. It is with its presence that the dangerousness of the disease is connected. Pharyngeal changes which resemble the local diphtheria alterations, but are accompanied with, or engendered by, cocci, represent a disease which differs entirely from diphtheria (diphtheroid[1]). The latter is not very dangerous. Mixed infections, in which the Loeffler bacillus is met with large numbers of cocci, are the most dangerous forms. Many of them take a septic course.

2. Diphtheria is very contagious, and is transmitted both by direct contact with the sick and by objects to which the bacillus clings with great pertinacity. On that account measures of precaution against the spreading of the disease are demanded, and ought to be legalized and enforced.

3. Antitoxin ("Heilserum") has proved thoroughly efficient, and the best of all the remedies thus far employed against diphtheria.

4. The method of injecting is exactly like that of making subcutaneous injections in general. Strict asepsis is required.

5. Antitoxin is the more effective the sooner after the first appearance of diphtheria it is employed. Its employment ought to be combined with the local cleansing—aseptic—treatment now in use, which is both rational and efficacious. This combined method has reduced mortality to one-third of the former death-list.

6. The dose of the remedy depends on the earlier or later time of its administration, on the severity of the infection, and the age of the patient. It amounts to from 600 to 4,000 antitoxin units. It is best to employ the full dose at once; still an additional administration is advisable in an obstinate case.

7. The effect of the remedy is visible in the limitation of the local process, and later on in the rapid loosening and removal of the morbid products, and in the improvement of the general condition. The first symptom of this improvement is the reduction of the fever.

8. The remedy is most efficient in the cases of non-septic diphtheria; still, mixed infections—septic diphtheria—are also favorably affected by it. They demand rather larger doses.

9. The administration is not complicated with serious accidents and subsequent diseases. Exanthems have often been observed, but, though they were accompanied with glandular tumefactions or joint affections, they proved devoid of danger. The antitoxin does not cause renal or cardiac disease.

10. For the present a conclusive opinion on the value of antitoxin as a preventive cannot be given. The doses of antitoxin—such as are recommended for immunization—being small its use for that purpose is to be recommended.

11. The therapeutical value of antitoxin being securely established by empirical observation, the absence of positive knowledge as to its *modus operandi* in the system is of no account.

It will be noted that "pharyngeal changes which resemble the local diphtheric alterations but are accompanied with or engendered by cocci, represent a disease which differs entirely from diphtheria," and is therefore called diphtheroid. We suggest that there is no resemblance "but a perfect equality of the pseudo-membranes in the two classes, in regard to fibrine, epithelial changes, blood-cells, leucocytes, etc.; with the exception that the membranes—perfectly equal in all cases—exhibit in the external layers of many of them the Loeffler bacillus (sometimes very, sometimes moderately, sometimes not at all virulent)—in many, however, streptococci, and in others (the worst form) both bacillus and streptococci. The anatomical condition of the membranes is identical with the exception of the microbe contained therein, and it is the microbe, and not the anatomical structure, and not the clinical features, which have been taken as the most pathognomonic element of diphtheria. This disease and its name existed long before the microbes were known or differentiated, and the clinical features of diphtheria were as well understood then as to-day. Indeed, Gerhard (and Jacobi after him) appreciated the possibility of several causes of what was known as diphtheria. Now, since the differentiation of the microbes it has become the usage to call diphtheria only those cases which depend on, or are connected with, the Loeffler bacillus. To what extent this postulate is justified remains to be seen; to day, however, it is frequently no longer considered a postulate but an axiom, and those who hesitate to take the former as absolute gospel are deemed heretical, in spite of the recognized fact that even the very Loeffler bacillus is not always virulent, but sometimes mild-mannered and powerless.

We can hardly find fault with the author for not giving more than five pages to the consideration of the "former treatment." Three pages, however, are not sufficient to give the least idea of what has been, or can be accomplished, by both internal and mild, but persistent and appropriate local treatment; still, we must not forget that whatever Baginsky says as an introduction to his main object cannot be expected to take an important place in his book, which has been written for a special purpose. Otherwise, the mercurial treatment, such as it has been introduced among us since 1884, by Jacobi, and tried and eulogized by scores of others here and abroad,[1] with its remarkable effects both on the course of the disease and its mortality, would have deserved a more prominent consideration and greater appreciation. Indeed we have met with many a practitioner in New York who felt he had no use for antitoxin as long as his cases, both naso-pharyngeal and laryngeal, did well under mercury and intubation.

Under the heading of diphtheria, Baginsky no longer comprehends only those cases which exhibit membranes of large size, but also such as were often denied its full rank and dignity. These thirty-five years Jacobi has been teaching among us, and has published a number of times the empirical fact, that very many cases of "catarrhal" pharyngitis and follicular or "lacunar" angina were really diphtheritic, not only

[1] This term was first used by French authors, and introduced into German literature by Baginsky, and after him by Escherich.

[1] T. B. Bennie, M.A., M.D.: Some Remarks on the Treatment of Diphtheria by Mercurial Salts. Australian Medical Journal, January 20, 1895.

leading to further and more legible symptoms, such as nasal and laryngeal diphtheria, but also terminating in paralysis of the patient, and contagion among his neighbors. Koplik proved the correctness of this claim by bacteriological researches, and Baginsky again confirms these multiple features of diphtheria by subjecting every actual or suspect case to bacteriological examination. Thus the suspicion expressed by many that the European observers, in order to prove the claims of antitoxin, were liable to treat selected cases only, and perhaps even such as were not even proven to be diphtheritic, is not justified. It is true that the presence of a bacillus on a healthy mucous membrane does not constitute diphtheria, but a sore or catarrhal mucous membrane and a tuft of membrane on a tonsil which harbors bacillus certainly do so.

Of his many cases of diphtheria treated with ("serum") antitoxin, Baginsky has published several series, and discussed them, mainly in the Berlin Medical Society. Indeed there is no name more prominently connected with the whole subject than his; and the book he now presents is not the least contribution to pediatrics offered by a most active, conscientious, and justly famous practitioner and teacher. His whole number of cases treated with antitoxin was 525, of which 83 died (15.8 per cent.). Eleven of these were moribund on admission and died within twenty-four hours. Dysentery, croup, and pneumonia were the cause of death in 26, heart failure in 8 cases. The latter was observed in 5.69 per cent. of the 525 cases treated with serum, in 10.9 per cent. of the 993 cases treated without it in the years 1891–94. In regard to albuminuria and nephritis some difference appears to exist between the cases treated with or without antitoxin. In 525 cases treated with serum there was albuminuria in 40.95 per cent., clinical nephritis in 12.57 per cent., post-mortem nephritis in 15.80 per cent.; in 993 cases, without serum, albuminuria in 42 per cent., clinical nephritis in 25.78 per cent., and post-mortem nephritis in 16.31 per cent. Thus in the author's cases there is certainly the proof of rather a favorable inference in regard to renal complications.

It is impossible to enter into a full consideration of the great many facts and observations contained in the book in a review which can do no justice to its merits; but still we ought to refer to the observations made during the course of a number of years on cases of laryngeal stenosis. Since the inauguration of the hospital a large number of tracheotomies and intubations were performed. The latter were often followed by tracheotomies, because of the increase of the threatening symptoms; thus the latter was mostly preferred. From 1890 to the end of 1894 there were 1,258 cases of diphtheria; 418 tracheotomies were performed, and 135 intubations, with a total mortality of these 553 operations of 59, sixty-two per cent. Of 418 tracheotomies the mortality was 64.4 per cent.; 77 of them were performed after previous intubations (mortality of these 77, sixty-nine per cent.); 58 intubations without secondary tracheotomy had a mortality of 41.8 per cent.

This condition of things was changed with the beginning of the antitoxin treatment. The author says that no child (one exception) entering upon the treatment without laryngeal stenosis developed it afterward. Thus the number of operations became less. Among the 525 cases treated with serum there were 53 tracheotomies with 34 deaths, and 54 intubations with 2 deaths. Tracheotomy had to be performed 12 times after previous intubations; in these 12 there were 9 deaths. There were altogether 68 (sixteen per cent.) recoveries after the two operations. From the facts at his disposal Baginsky concludes that under the influence of the antitoxin treatment intubation becomes a full equivalent of tracheotomy; that, indeed, the latter has been replaced by the former, and is reserved only for the very worst cases, either as a last resort or for the purpose of euthanasia. Evidently intubation is steadily conquering larger fields and gathering more laurels.

A Text-book of Physiology. By M. Foster, M.A., M.D., LL.D., F.R.S., Professor of Physiology in the University of Cambridge. Revised and Abridged from Author's Text-book of five vols. 8vo, pp. 1183. New York and London: Macmillan & Co. 1895.

We have from time to time expressed our high appreciation of the author's work in connection with each of the five volumes which have already appeared. In that form no work of its size has compared with it in thoroughness of scientific detail and practical value. The whole ground has been so thoroughly covered that nothing was left to be desired. It is sufficient to say now that the present volume contains all the really essential excellences of the greater work, which is thus placed within the reach of the ordinary student who may not be able to purchase the entire series. This service will be especially appreciated by everyone who wishes to possess one good book that is up to date and contains all that is new in its particular department.

Ein Neues Heilverfahren bei Netzhautablösung. Von Professor Dr. R. Deutschmann. Hamburg and Leipzig: Leopold Voss. 1895.

This is an interesting monograph upon the treatment of detachment of the retina, which appeared originally in the *Beitrage zur Augenheilkunde*. The author reports some excellent results.

L'Insomnie et son Traitement. Par le Dr. Maurice de Fleury, Ancien Interne des Hôpitaux. Paris: Société d'Editions Scientifiques. 1894.

The author of this brochure holds that the use of drugs should occupy a wholly secondary rank in the treatment of insomnia, the main reliance being placed upon hygienic measures. He argues well in support of his belief, which all must admit to be sound, but what is of more importance he seems to prove that hygienic measures will usually suffice to produce the desired effect.

A New Method of Inhalation for the Treatment of Diseases of the Lungs. By W. H. Spencer, M.A., M.D., M.R.C.P., Consulting Physician to the Bristol Infirmary; Late Lecturer on the Principles and Practice of Medicine at the Bristol Medical School. London: The Scientific Press, Limited. 1895.

In this little book Dr. Spencer argues for the necessity of making applications to the lungs of medicaments in the form of a vapor, as that is the only form by which the entire surface of the respiratory tract will be reached. He has devised a vaporizer, in the form of a water-bath, by means of which the remedy may be volatilized and the air of the room be kept constantly saturated with its vapor.

Ozena Verdadero (Rhinitis Atrófica Fétida). Por el Dr. Avelino Martin, ex-Alumno Interno Pensionado y Premiado de la Facultad de Medicina de Barcelona, etc. Barcelona: Luis Tasso. 1894.

In this little work of about one hundred 16mo pages Dr. Martin presents a very clear picture of the distressing and obstinate disease. The principal object of the work is, however, to enter a plea in behalf of vibratory massage as a remedy for atrophic catarrh. The author believes thoroughly in this method of treatment and argues well in its favor.

Coleccion de Artículos de Medicina. Por el Dr. Enrique Lopez. Habana: La Commercial. 1895.

This is a collection of articles written on various occasions and published by Dr Lopez in different literary

and medical journals in Cuba. Many of them which deal with the history of medicine in that island are of great general interest. Most of the others are on subjects relating to ophthalmology. One is a brief biographical sketch of Dr. Herman Knapp, written on the occasion of his visit to Havana in the spring of 1889.

Manual of General Medicinal Technology, Including Prescription-writing. By Edward Curtis, A.M., M.D., Emeritus Professor of Materia Medica and Therapeutics, College of Physicians and Surgeons, Medical Department of Columbia College, in the City of New York. Third Edition, conforming to the United States Pharmacopœia of 1890. New York: William Wood & Co. 1895.

This little work is one of the best of its kind, owing to the clear arrangement of the subject-matter and to the easy colloquial style of the author. By its aid a student must be dull indeed who cannot master the art of prescription-writing in a short time. The second part, which deals with the modes of medicating and dosage, contains points which even an old practitioner might profitably make note of. The book, though nearly two hundred and fifty pages in length, is of a size to be carried in the coat-pocket, so that one may carry it about with him until he has thoroughly assimilated its contents.

Third Annual Report of the Board of Health of the State of Washington. Olympia: O. C. White, State Printer. 1895.

In addition to the usual statistics of births and deaths this volume contains a brief report on the contagious diseases in cattle.

Eighteenth Annual Report of the Board of Health of New Jersey. Trenton: MacCrellish & Quigley. 1895.

This volume contains several interesting papers and reports, notably one on the causation of disease by milk. An appendix contains the report of the Bureau of Vital Statistics of New Jersey for 1894—a useful addition to statistical literature.

Hygiene and Physical Culture for Women. By Anna M. Galbraith, M.D., Fellow New York Academy of Medicine, etc. 12mo, pp. 294. New York: Dodd, Mead & Co. 1895.

This little book presents the subject in an attractive and intelligent manner and is sufficiently expressive in the statement of well-known scientific facts to convince any lay reader with the reasons of the faith of the author. Every topic is clearly explained from a physiological as well as anatomical basis, and only such points are presented as are necessary to know in order that the most casual reader can appreciate the full force of the reasons why. There are very excellent chapters on the evils of the present dress of the female, particularly referring to the corset and shoe, and many admirable injunctions regarding the proper use of the various bodily functions.

A Manual of the Modern Theory and Technique of Surgical Asepsis. By Carl Beck, M.D., Visiting Surgeon to St. Mark's Hospital, New York. 12mo, pp. 306. Philadelphia: W. B. Saunders. 1895.

This little work is a compendium of the present status of asepsis and its relations to operation and wound-healing. The author with painstaking spirit dwells exhaustively on all the details, elementary and perfected, that refer to the general subject under the following headings: "Influence of Microbes," "Importance of Asepsis," "Means of Disinfection," "Prophylactic Disinfection," "Disinfection of Instruments and Dressings," "Sterilization of Catgut, Silk, Sponges, Drainage-tubes," "The Aseptic Operating-room," "Aseptic Open-wound Treatment," "Renewal of Dressings," "Technique of an Aseptic Operation," and lastly he gives an excellent chapter on "Anæsthesia."

Dissections Illustrated. A Graphic Hand-book for Students of Human Anatomy. By C. Gordon Brodie, F.R.C.S., Late Senior Demonstrator of Anatomy, Middlesex Hospital Medical School, London. With plates drawn and lithographed by Percy Highley. In Four Parts. Part IV. The Abdomen. 4to, pp. 142. London and New York: Macmillan & Co., Whittaker & Co. 1895.

Part IV. comprises sixteen colored plates of the abdominal and pelvic regions, about two-thirds natural size, and thirteen diagrams, and completes the series. On previous occasions we have noticed the different parts in the regular order of their appearance—I. The Upper Limbs; II. The Lower Limbs, and III. The Head and Neck. As will be remembered their illustrations are reductions of the larger and well-known plates of Ellis & Ford, and intended to make a work of cheaper and more convenient size and thus one that can be within the reach of the ordinary student and general practitioner. It is unnecessary to allude to the excellence of these illustrations farther than to say that they are faithful and accurate representations of the originals. In this respect we are only repeating what has been already said of previous sections. The present part contains detail dissections of the superficial and deeper abdominal and pelvic regions, male and female, and also of the perineum. Altogether the work will serve its purpose of refreshing the memory and bringing up the exact topography of the parts involved in an operation when no cadaver is obtainable for rehearsal.

Epitomes of Modern Surgical Progress for Students and Practitioners—Urinary Surgery. By E. Hurry Fenwick, F.R.C.S., Eng., Surgeon to the London Hospital, etc. 12mo, pp. 219. Bristol: John Wright & Co. London: Simpkin, Marshall, Hamilton, Kent & Co.

Every student of genito-urinary surgery will appreciate this valuable epitome by Mr. Fenwick. He has taken pains to condense in this small volume accounts of all the recent advances in this progressive field of surgery, giving the technique of all the newer operations and novel manipulations, and has altogether presented a mass of valuable practical information on the subjects nowhere else to be found in any convenient compass. The book is a record of progress along the different lines of study taken by the advanced workers, and is divided into the following sections: Surgery of the Kidney, of the Ureters, of the Bladder, Electric Cystoscopy, Diseases and Operations on the Prostate, and Diseases of Urethra and Seminal Vesicles.

On Diseases of the Vermiform Appendix. With a Consideration of the Symptoms and Treatment of the Resulting Forms of Peritonitis. By Herbert P. Hawkins, M.A., M.D., Oxon., F.R.C.P., Assistant Physician and Lecturer on Pathology at St. Thomas's Hospital. 8vo, pp. 159. London and New York: Macmillan & Co.

This is a dissertation presented to the University of Oxford for the degree of Doctor of Medicine in 1894, and is an excellent review of the subject, particularly in its pathological, statistical, and therapeutical bearings. A very full history of the affection is given, and all the important data connected therewith are presented in chronological order. The anatomical and pathological conditions are elaborated with much painstaking accuracy, and numerous well-executed illustrations demonstrate very satisfactorily the bacteriological association with gross lesions. The symptomatology is presented in a clear manner, and the treatment, both medical and surgical, is on a properly conservative basis.

NOTE-BOOK OF MATERIA MEDICA, PHARMACOLOGY, AND THERAPEUTICS. By R. E. SCORESBY JACKSON, M.D., F.R.S.E. Fifth edition. Revised by J. RUTHERFORD HILL, Assistant Secretary of Pharmaceutical Society, and RALPH STOCKMAN, M.D., F.R.C.P.E., Lecturer on Materia Medica, School of Medicine, Edinburgh. 12mo, pp. 743. Edinburgh: James Thin. London: Simpkin, Marshall & Co. 1895.

THE well-established reputation of this valuable and practical manual has been for a long time unquestioned, and it is only necessary to add that the present volume holds its own in being fully up to date and containing everything necessary in a work of its kind.

Therapeutic Hints.

Biliary Calculi with angiocholitis, chills, fever, etc., four to seven grains of calomel every two or three days.—RANGLARET.

Vomiting of Pregnancy.—Paint os with cocaine, or give by mouth, combined with antipyrin:

℞. Chlorhyd. cocaine ..... gr. iss.
Antipyrin ..... gr. xvj.
Aq. dest. ..... ʒiv.
Sig.: Teaspoonful every half hour until the vomiting ceases.

—LUTAUD.

Tapeworm.—Low diet for one day; on morning of second, in three doses at intervals of fifteen minutes:

℞. Honey ..... ʒv.
Ethereal ext. pomegranate,
Eth. ext. male fern ..... āā gr. viiss.
Kousso flowers ..... ʒv.
M. Sig.: Divide into three parts.

—DROUKE.

Chloral may be disguised in gaseous bottled lemonade.—HOLLAND.

Duboisin is most useful as a hypnotic in insomnia caused by intense motor excitation. Hypodermic, $\frac{1}{150}$ to $\frac{1}{75}$ grain.—SKURIDIN.

Pneumonia in Children.—To relieve irritability and restlessness, and to get free elimination and a good action of the kidneys, use

℞. Vini ipecac ..... ʒj.
Potass. citratis ..... gr. xxx.
Tr. opii camph. ..... ℥ij.
Elixir simplicis ..... ℥j.
Aquæ dest. ..... q.s. ad ʒiv.
M. Sig.: A teaspoonful to an infant six months old every two hours.

—FRANK S. PARSONS.

Dry Tongue in diabetics, etc.—

℞. Pilocarpin. nitrat. ..... gr. ½.
Spirit. vini dilut ..... ♏xx.
Aquæ ..... ʒj.
M. Sig.: The tongue is to be moistened with five or six drops of this solution four or five times daily.

Gonorrhœal Cystitis.—

℞. Pyoktanin ..... gr. xv.
Boiled distilled water ..... ℥ij.
M. Sig.: Inject morning and evening for ten to fifteen days.

—LUTAUD.

Rachitis.—

℞. Phosphorus ..... 0.01.
Cod-liver oil ..... 100.
Saccharin 5
Essence of lemon ..... gr. ij.
Teaspoonful daily.

—GUINON.

Salophen in acute articular rheumatism when the salicylates are not tolerated. One gramme three or four times daily.—HOLZSCHNEIDER.

Citric Acid, 1 to 100, injected six times daily in urethritis, cures in five to eight days.—PELLISSIER.

Eczema of the Vagina.—

℞. Ichthyol ammon. ..... 1½ to 2 parts.
Amyli tritici,
Zinc. flor. ..... āā 12 parts.
Vaseline ..... 25 parts.
M. et fiat pasta.

—VON SEHLEN.

comfort in such a [illegible] there are more doctors than lawyers who are doing ordinarily well. In the average way, the physician has the better chance of [illegible]

Erysipelas.—An antitoxin elaborated through the mule has just been discovered by Dr. Roger.

Burns.—

℞. Lanolin ..... 10.
Adipis benz. ..... 20.
Aq. calcis ..... 30.

—UNNA.

Sciatica.—

℞. Tr. aconite,
Tr. colchica sem,
Tr. bellad.,
Tr. actea racem ..... āā p. e.
M. Sig.: Six drops every six hours.

—METCALF.

Hemoptysis.—One and a half to two and a half grains of chloral per rectum if the heart is sound.—PÁL.

Thiosynamin for injection into contracted cicatrices and chronic glandular enlargement.—UNNA.

Horse-radish Spirits as a wash along with other means in rosacea.—PURDON.

Corns.—

Trim your corn in the gray of the morn
With a blade that's shaved the dead,
And barefoot go and hide it so
The rain will rust it red:
Dip your foot in the dew and put
A print of it on the floor,
And stew the fat of a brindle cat,
And say this o'er and o'er:—
Corney! morny! bladey! dead!
Gorey! sorey! rusty! red!
Footsy! putsy! floory! stew!
Fatsy! catsy!
Mew!
Mew!
Come grease my corn
In the gray of the morn!
Mew! mew! mew!

—JAMES WHITCOMB RILEY.

The Benefits of Specialism.—Dr. W. K. Simpson, in *New York Medical Journal*, says: "After having considered the evident present tendency toward specialism, it might be well to consider the debt that the profession owes it. The relief from former ignorance and chaos has been the result of men devoting themselves to special work. The microscope and pathology are brilliant examples. Special surgery has allowed the exploration of regions of the body with impunity which in former times were closed to all knowledge, yielding results which seem but little removed from the miraculous. Look at it as we may, specialism is a natural culmination of the advancements made in the science and practice of medicine, and, as a result, gynecology, ophthalmology, neurology, orthopedics, laryngology, otology, dermatology, and many others have reared domains of their own which are far from being circumscribed; and it has not been the work of narrow-minded men, but men of broad minds and actions that have put specialism on a sure foundation and doubtless have made it the practice of the future."

Clinical Department.

PLACENTA PRÆVIA.

By J. E. VIRDEN, A.M., M.D.,

COCHRANTON, O.

On December 5, 1894, I was called to assist Dr. I. N. Bowman, of Upper Sandusky, O., in the delivery of Mrs. C. M——. Her history, as given by Dr. Bowman and the husband, is as follows :

ing to the United States Pharmacopœia of 1890. New York : William Wood & Co. 1895.

This little work is one of the best of its kind, owing to the clear manner in which it is written. The first edition appeared a few years ago, and the present one is a revised and enlarged edition of the former. The author has evidently had a large experience in the practical application of the principles of pharmacy, and has given us a book which is a credit to himself and to the profession.

first had pains for about two days, when the membranes ruptured and the pains ceased entirely ; for three or four days following this there was a continuous vaginal discharge, but no pains ; then the back began paining severely, and so continued until the attending physician removed a dead child at the end of one week from the first pains.

Her second confinement occurred about two years ago, when she was attended by Dr. Bowman. On the arrival of the doctor on this occasion he found the membranes ruptured and an arm and shoulder presenting ; he at once sent for his partner, Dr. McConnell, and while the patient was under an anæsthetic they turned and removed a dead child. Her recovery then was uneventful.

On December 5, 1894, Dr. Bowman was called to attend her in her third confinement. He arrived about 1 P.M., and learned that she had been having some pains since about 6 A.M. Her pains were regular, of good strength, and occurring about once in four minutes. A vaginal examination by him showed the cervix dilated one-third of its full extent and a large bag of waters protruding. Pains continued for some time, when the membranes ruptured spontaneously, discharging about one-half gallon of amniotic fluid. As soon as the membranes ruptured, the labor pains stopped entirely. A vaginal examination at this time showed the cervix soft and readily dilatable, and just internal to it was felt the placenta, covering it so completely that the edge could not be felt in any direction, but in the right inguinal region it seemed as if the fingers reached near the edge ; also hanging through the cervix was the collapsed sac that had contained the waters.

Not wishing to take the responsibility of completing the delivery alone, Dr. Bowman was sent for, and arrived at the bedside about 4 P.M. At this time the woman was resting comfortably, having a pulse of about 100, but was rather nervous. The uterus was in tonic contraction. Vaginal examination showed the cervix, placenta, etc., as stated to me by Dr. Bowman.

Our decision was to give an anæsthetic and deliver at once, and in such manner as would be indicated when the presenting part was discovered.

While I administered chloroform, Dr. Bowman, with one hand in the vagina, found the placenta attached entirely around the lower segment of the uterus, except in the right inguinal region, as before suspected. Pushing his fingers through this opening he was able to grasp a foot, and pulling it down, proceeded with the delivery as fast as thought prudent ; thus was soon born a living female child.

The cord pulsated until tied. The placenta was removed in a few minutes by Credé's method, and on examination it was found to be of about the usual size, and that about one-third had been situated to the right and two-thirds to the left of the cervical canal.

There was no hemorrhage, and I am sure the woman did not lose more than four ounces of blood besides that in the placental vessels. There had been no hemorrhage or other symptom during pregnancy to cause one to suspect placenta prævia. After the placenta had passed into the vagina she was given one drachm of fluid extract of ergot. After removing the soiled bedding, applying the binder, etc., we found her pulse to be 78. She was perfectly conscious and asked about her baby. The child's appearance was that of one born at term, and it weighed seven pounds.

The mother's recovery was uneventful.

A CASE OF TUMOR IN THE PONS VAROLII.[1]

By CHARLES E. NAMMACK, M.D.,

ATTENDING PHYSICIAN TO THE NEW YORK HOSPITAL, OUT-PATIENT DEPARTMENT.

Mrs. Annie O——, aged twenty-four, married two years, never pregnant, applied for treatment April 23, 1895. She has suffered for five months from constant headache, diffused and deep-seated, and increased by changes of posture, constipation, or mental annoyance. The headache is worse at night, causing insomnia. At the time the headache began she had noticed a gradual loss of power in the right arm and subsequently in the right leg, but no convulsive movement or spasm. She began to have vomiting every morning on arising from bed. Three months afterward she became unable to close the left eye, and noticed a peculiar appearance of the face. At this time she began to suffer from tinnitus aurium. She had also become afraid to go out-doors alone on account of a sense of giddiness and unsteadiness in walking. Her memory failed, and irritability of temper, alternating with depression and emotional excitability, developed. She has had no injury nor severe emotional shock prior to her present illness. She gives no history of alcoholism, rheumatism, or syphilis. Her husband absolutely denies having had any venereal disease previous to marriage. Tuberculosis or organic nervous disease cannot be traced in patient's ancestry.

Examination : Pulse, 120 and feeble, arterial tension low, left ventricle not hypertrophied. Urine is negative as regards albumin or sugar. No evidence of lead poisoning. No pulmonary or laryngeal tuberculosis. There is crossed hemiplegia, the right arm and leg being affected, with the left facial nerve. Patient answers questions slowly, and it is difficult to keep her attention concentrated on an idea. There is nystagmus when eyes are directed to the right. Ophthalmoscopic examination by Dr. Leroy Pope Walker shows optic neuritis on both sides, with beginning choked disc in left eye. Vessels very tortuous, veins engorged, no hemorrhages. Fundi otherwise normal. Vision, O. D. $= \frac{20}{200}$, O. S. $= \frac{20}{70}$, not improved by glasses. Patient staggers slightly to right in walking. The knee-jerks are exaggerated on both sides. The tongue is furred on the left side only. Taste is diminished on the anterior two-thirds of the tongue on the left side. There is neither motor nor sensory paralysis of the fifth cranial nerve.

The diagnosis is intra-cranial tumor. Localization, lower part of pons on left side. Nature, gumma.

Patient was ordered two ounces of blue ointment to be used by inunction, and iodide of potassium ten grains, three times a day, to be increased five grains daily until relief to symptoms or intolerance of drug had developed. One week later she reported headache absent except on getting out of bed in morning ; vertigo less, tinnitus less. Her mental faculties are considerably brighter. No symptoms of iodism from sixty grains three times a day.

29 East Twenty-fourth Street.

[1] Patient presented before the New York Neurological Society, May 7, 1895.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, June 29, 1895.

THE WORK AND THE PAY.

THE popularity of medicine as a profession is always emphasized at this season by the number of graduates that make their bow with diplomas in hand before large and appreciative audiences on the numerous commencement occasions of the different medical departments of our universities. In fact, the medical graduates outnumber all the others. That the medical departments are the largest in most of the institutions of learning requires no demonstration. It is not difficult to explain why this is so, for no profession offers in its practical pursuit, or rather its conscientious study, better opportunities for substantial mental culture, greater satisfaction in its work, or a wider independence of opinion in the broad and liberal interpretation of its principles. But while it is the grandest of professions, it is certainly the meanest of trades. If the work is done for the work's sake, there is a continuous and ever-increasing satisfaction in its pursuit. It is this, indeed, that lends fascination to drudgery and contentment to comparative impecuniosity. All cannot be great physicians, but there is no reason why all cannot be good ones. The latter is the only real incentive for the young man who is willing to take the exceptional chance of making a trifle more than a good living. The rewards are not to be measured on any conventional money basis. To such as imagine otherwise there is left nothing but disappointment.

Not long ago we took occasion to study the question of the average income of the physician, and, although prepared in some respect for the answer, we were, nevertheless, surprised at the figure. Notwithstanding the amount compared favorably with that received by the average minister or lawyer, it was much below what might have been expected from the boasted returns of would-be prosperous practitioners. The difficulties in the way were obvious enough, but were in a measure offset by the study of certain known standards of available business with possible and actual returns therefrom. Comparatively few in any city or district rendered themselves liable to the threatened income tax. The average yearly income for the country town was from fifteen to eighteen hundred dollars, while that for the city was scarcely above two thousand. Allowance was duly made for bad debts, the latter averaging from thirty to fifty per cent. of all gross earnings.

In large cities there were a goodly number with an income ranging from three to five thousand dollars, but beyond these figures, in the averages from five to twenty-five thousand, there were very few indeed; while above these amounts there were scarcely enough to count on the fingers of one hand. Although high fees in law are far beyond those in medicine, the average lawyer more than strikes a comparative compensation at the other end of the line. The law of average is as certainly balanced between these two extremes as is any purely mathematical equation. The comfort in such a contemplation is that there are more doctors than lawyers who are doing ordinarily well. In the average way, the physician has the better chance of making a fair living.

It is the ordinary every-day fee in the usual and steady run of regular business that gives the doctor his real dependence, rather than the occasional larger amount for an extraordinary service. Surgical operations, while they command higher rates, are comparatively few and far between, and are always offset by the lavish expenditure of time and work in the hospitals for the necessary experience and requisite reputation for such business. But worse than all, for purposes of income the very means used to obtain skill directly militate against the possibility of remunerative returns in the end. Most of the important operations are done in hospitals for nothing and for the sake of the practice; and even the paying classes take advantage, eagerly and persistently, of the situation. This will be more and more the case so long as our hospitals advertise free medical and surgical treatment and our millionaire clinics gather in the pay patient under the guise of clinical material.

From the stand-point of money-getting the doctor has by no means an easy road to wealth. The only comfort is that he is satisfied with little, and is, therefore, comparatively rich; but best of all his work always carries with it a hearty taste, and its steady progress the fuller fruition of a lofty purpose.

THE LEGISLATIVE WORK AND INFLUENCE OF MEDICAL SOCIETIES.

WE are indebted to the excellent summaries of the proceedings of a number of State medical societies in the *Medical Standard* for facts recording the business and legislative work of these organizations. A State medical society nowadays rarely meets without passing resolutions in regard to some proposed legislative work or without the preparation and indorsement of some bills which they hope will be made laws.

The American Medical Association did its share by the introduction of a resolution authorizing the appropriation of $1,000 for the purpose of securing a national board of health. This resolution was naturally referred to a committee, and did not reappear. The American Medical Association is not rich enough to spend its money in chasing rainbows; and it is, we feel sure, very unwise for it to continue passing empty resolutions to the effect that there ought to be a department of public health when it is very well known that such a department cannot be established for many

years, while a very effective bureau of health could be created within a much less time.

The Montana State Medical Association occupied itself in discussing the need of a State board of health, and a committee was appointed to draft a bill in order to secure such an organization.

The Arkansas State Medical Society passed a resolution condemning the State Legislature for passing a bill which confers upon county judges the power to admit to the practice of medicine any applicant who presents himself, whether he be a graduate of medicine or not

The Illinois State Medical Society through its chairman of the Committee of Legislation reported upon three bills: One providing for changing the law relating to expert testimony, one providing for the establishment of an asylum for epileptics, and a third amending the laws in relation to the sale of poisons. These three bills had all been introduced into the Legislature, but none of them had yet been enacted into laws.

The Pennsylvania State Medical Society has memorialized the Legislature for more efficient provision for registration of vital statistics.

The Ohio State Medical Society has a special committee on State Medical Legislation composed of one member from each county auxiliary medical society in the State. This special committee recommended to the State Society that it approve the Mosgrove Bill regulating the practice of medicine in the State of Ohio, and the Society adopted the recommendation and appointed a committee to take charge of the measure.

It will be seen that the legislative work of our State societies is mainly concerned with the securing of better laws regulating the practice of medicine, better provision for medical education, and better provision for the work of State boards of health. In all these departments the work has been of a kind which tends to benefit the State and society, and there is no question but that our State medical organizations are becoming an important and useful factor in promoting the welfare of our republic. It can easily be seen, also, that they are more important bodies in the community than they used to be. Their attempts at securing legislation are not now met with contempt by the politician, as was often the case.

BICYCLING FOR WOMEN.

The *Boston Medical and Surgical Journal* contains an article on this ever-present subject by Dr. Charles W. Townsend, and another by Dr. James R. Chadwick. Dr. Townsend's article is based upon the results of a series of inquiries made to a number of female physicians residing in Boston and Massachusetts. Eighteen answers were received. All but one of the writers stated decidedly that they considered bicycling of value to the average woman under proper conditions. Nine had seen no harm from bicycling. The others reported some minor troubles due to intemperate exercise. One had seen a serious ovarian trouble directly due to riding long distances at about the menstrual period. One reports a case of renal hemorrhage, a case of hemorrhage of the womb, a case of inflammation of the ovary with anteflexion, and a case of miscarriage. The question "Would you advise the bicycle in any form of uterine disease?" was answered in the affirmative by all but two. A number of cases are reported showing improvement in retroverted and also in enlarged and even prolapsed uteri. Several speak of the beneficial use of the bicycle in patients to whom walking was difficult or impossible. "It is interesting to note," says Dr. Townsend, "that the favorable criticisms were not obtained from bicycle enthusiasts, as only one of the physicians had used a bicycle herself."

Dr. Chadwick's article is devoted mainly to the subject of bicycle saddles for women. His attention was called to this subject from having seen two cases in which badly fitting saddles had produced leucorrhœa and vulvitis. Dr. Chadwick states that no serious attempt had as yet been made to produce a saddle adapted to woman's anatomy. The result is that women have generally had great difficulty in having a saddle so adjusted as to be rendered comfortable, in other words to avoid pressing unduly on the vulva. Dr. Chadwick's opinion seems to be that bicycle saddles should be especially made for women, that they should have as little projection in the front as possible. With a properly fitting saddle, he considers bicycling an excellent mode of exercise.

MR. HERBERT SPENCER ON THE EVOLUTION OF THE MEDICAL PROFESSION.

In a series of articles on professional institutions in the *Contemporary Review* Mr. Spencer takes up the subject of the medical profession. He traces the origin of the art, its early association with the clergy, its gradual separation from the sacerdotal authorities and the organization of the profession by itself, and finally the differentiation of the specialties. Mr. Spencer writes what would seem to be a very ordinary essay on the history of medicine if it were signed by any other name than his own. He shows, however, in his final estimate of the status of the medical practice that he has a broad sympathy which includes the quack and the regular practitioner, for he says that the incorporation of authorized practitioners has developed a sort of trades-union spirit which leads to a jealousy of the unincorporated practitioner—*i.e.*, irregular. Like the religious priesthood, he says, the priesthood of medicine persecutes heretics and those who are without diplomas. In America the persecution of heretical practitioners has undoubtedly existed, but it is passing away, and on the whole we think that the charlatan in this country has still a pretty easy time of it, and never has suffered very much.

Uniformity in Electrodes.—The committee on electrodes of the American Electro-therapeutic Association has addressed a circular letter to all the manufacturers of electro-therapeutic apparatuses in the endeavor to secure the universal adoption of uniform connections, a standard gauge of screw throughout construction, and efficient, durable, simple, and interchangeable electrodes.

News of the Week.

Some Features of the Present Medical Law.—In an article relating to some features of the present medical laws of New York State, recently published in this journal, the wording was such as to make possible the inference that on and after August 1, 1895, a new scheme of registration for old practitioners would go in effect. For the benefit of those who may have thus interpreted the article in question we would state that a legal registration in a county clerk's office in this State entitles one to the right at all times thereafter to practise in that county, unless the original license or diploma is revoked for conviction of felony or other cause. The article referred to dealt only with those who had never previously registered here, but who proposed at some future time to enter the State as medical practitioners.

Rheumatic Appendicitis.—Dr. Brazil and Dr. J. E. Frazer, of England, have published several cases of what they call rheumatic appendicitis, in which they think that the inflammation of the appendix is due to uratic deposits. These cases when treated by salicylate of soda are relieved with magical rapidity.

The Doctor in Athletics.—It looks now as though Dr. William G. Grace were likely to have a larger testimonial for having made two hundred runs at cricket than our most distinguished medical men have ever had for years of successful professional work. One of the London daily papers has started a testimonial fund, and it is stated that nearly $10,000 have already been collected.

Ptomaine in the Urine of Cancer Patients.—M. Griffiths has discovered a ptomaine in the urine of cancerous patients. It is a white substance, crystallizing in needles, and has an alkaline reaction. It is very poisonous, and is said never to be present in normal urine.

Death of M. Verneuil.—The death of the celebrated French surgeon, M. Verneuil, is announced. He was the oldest of the French surgeons and had filled all the higher officers of his profession in Paris, having been Professor of the Faculty, Surgeon of the Hospital, Member of the Academy, and President of the Surgical Society. M. Verneuil was one of the most illustrious of French surgeons at a time when to be a French surgeon was not a very illustrious thing. Late in life he retrieved some of his past by adopting Listerism. He was a man of great talent, an eloquent teacher, and a great clinician, but if he had lived in any other country than France he would have been called provincial. Provincialism, however, in France goes by some under the name of patriotism and by others under the name of Chauvinism. M. Verneuil was both a patriot and a Chauvinist.

The Medical Department of Georgetown University has just made a radical change in its courses. All future matriculates will have to attend day lectures and the clinics. This action will lessen the output of sunset doctors.

Doctor of State Medicine.—Rush Medical College, of Chicago, announces that it will give the degree of Doctor Medicinæ Civitatis, or Doctor of State Medicine. The degree is a graduate degree and the candidate must be a Doctor of Medicine of no less than one year's standing. The candidate must have completed, subsequent to registration, six months' practical instruction in a laboratory approved by the Faculty, and also have studied practical out-door sanitary work for four months under an approved officer of health.

Dr. F. L. Forsyth, of Providence, R. I., died on May 11th, aged forty-one.

A Medical Mayor.—Dr. A. W. Fly has been re-elected Mayor of Galveston, Tex.

The Coalition of Free Coinage and Medicine.—One of the Texas medical journals offers to send a free copy of "Coin's Financial School" to every new subscriber.

A Naval Surgeon and a Crazy Captain.—English journals report the case of an English naval surgeon who has recently been court-martialed because of a dispute arising between him and the captain. The dispute arose about the position of an operating-table, and the captain became so excited that the surgeon considered him to be mentally affected and unfit to command the vessel. He therefore ordered him on the sick-list. The captain refused to go and placed the surgeon under arrest. The court refused to allow any evidence on behalf of the surgeon on the question of the captain's health, and after a short consultation, found the surgeon guilty and ordered that he be dismissed from the service. Great indignation is felt at the verdict and mode of conducting the inquiry, and an effort will be made to challenge the decision. The case suggests one of a similar kind that recently occurred in this city.

Professor Trendelenburg has been called to take Professor Thiersch's place in Leipsic. Professor Mikulicz takes Professor Trendelenburg's place in Bonn.

Nosophen and Antinosin.—These decidedly unpoetical names have been given by Drs. Classen and Loeb to a combination of iodine and phenolphthalein. Nosophen is a dark yellowish, odorless powder, insoluble in water. Antinosin is a blue powder slightly soluble in water. Both preparations are said to be without any poisonous effects. They are recommended very highly in the treatment of nasal affections and as antiseptic powders to be used in dressing wounds. They are, in other words, recommended as substitutes for iodoform.

The Warm Bath in Insomnia.—According to Dr. Eccles, the use of the warm bath for the purpose of producing sleep is very efficient if properly carried out. The bath should be administered in a room whose temperature is 65° to 70° F. The patient is made to stand with his head over the edge of the tub, and his head and face are then rapidly douched with water at 100° F. The cooling of the body by the air and the hot sponging of the head send the blood to the head, dilating the vessels of the entire brain. The entire body is then immersed, except, of course, the head, in a bath at 98° F., which is rapidly raised to a temperature of 105° to 110° F. In a few minutes the patient

is taken from the bath, wrapped in warm blankets, and, without exertion on his part, taken to his room. The blankets absorb the moisture; in his room his night-clothes are put on, a warm bottle placed at his feet, and possibly some warm liquid food administered. The sedative and refreshing result is often most marked.

Dr. Richard Dewey, formerly superintendent of the Kankakee Hospital for the Insane, has accepted the position of superintendent of the Milwaukee Sanitarium at Wauwatosa.

The Various State Medical Examiners and Licensing Boards have organized into a National Association with W. W. Potter, M.D., of Buffalo, N. Y., as president and Dr. B. M. Griffith, of Springfield, Ill., as secretary. The object of the association is to establish a uniform schedule for all medical colleges and examining boards and to assist in perfecting a method for higher medical education.

The French Exposition of 1900.—According to *Le Progrès Medical*, the organizers of this exposition have made elaborate preparation for the police and everything else, but have entirely forgotten the medical service. "They have," says our contemporary, "taken great care to protect the houses, but they do not concern themselves with men. Is it that they consider human life so small a thing, or is it because they fear to imitate the Americans?" It would plainly be a very good thing if they did. The medical service at the Chicago Exposition was acknowledged to be a model of its kind.

Thalassotherapy.—We have all kinds of international congresses, but perhaps the most curious one, at least the one with the most Hellenistic name, is the International Congress of Thalassotherapy which met at Bologne in July last and is to meet again in August 27th to the 31st. The two principal questions which are to be discussed are: 1. Pulmonary consumption on the sea-borders, and 2, the technique of sea-bathing for disease.

An International Congress Against the Abuse of Alcoholic Drinks will be held at Bâle, August 20th. The discussions of the Congress will turn upon the subject of alcohol in its moral, hygienic, medical, and social relations, and the means, preventive, persuasive, and coercive, that can be used in combating alcohol.

Death of Dr. Carl Thiersch, the Eminent German Surgeon.—Dr. Carl Thiersch died on May 28th, at Leipzig, aged seventy-three. He was a native of Bavaria and was educated at the University of Munich, graduating in 1846. He afterward resided successively in Berlin, Vienna, and Paris. He was a frequent contributor to the literature of his profession, and the system of skin-grafting which he introduced is now generally adopted by surgeons throughout the world. He also wrote upon maxillary necrosis from phosphorus and upon Listerian methods in surgery.

Colleges with Four-year Courses.—The colleges of Washington should be added to the list of four-year medical schools recently published in our columns, as we are informed by an esteemed correspondent in that city.

The Mississippi Valley Medical Society will hold its twenty-first annual meeting at Detroit, on September 3, 4, 5, and 6, 1895. The railway companies promise a round trip for one fare to members attending the meeting.

Dr. Lewis A. Sayre.—Our famous townsman has been again honored. The Société Belge de Chirurgie has elected him an honorary member as an acknowledgment of his great services to surgical science.

The Honorary Degree of Doctor of Laws.—At the recent commencement of St. Francis Xavier's College the degree of LL.D. was conferred on Dr. Francis J. Quinlan, of the New York Polyclinic.

Mitchell District Medical Society.—The forty-seventh semi-annual meeting of this Society will be held at the West Baden Mineral Springs Hotel, West Baden, Orange County, Ind., on Friday and Saturday, July 5 and 6, 1895. The president of the Society is Dr. Joseph Eastman, of Indianapolis; the secretary is Dr. George W. Burton, of Mitchell, Ind.

American Climatological Association.—At the twelfth annual meeting of this Association, held at Hot Springs, Va., on June 13, 14, and 15, 1895, the following officers were elected: *President*, Dr. J. B. Walker, of Philadelphia; *Vice-Presidents*, Dr. Charles E. Quimby, of New York, and Dr. James A. Hart, of Colorado Springs; *Secretary and Treasurer*, Dr. Guy Hinsdale, of Philadelphia.

Gift to a Cincinnati Medical College.—Mr. and Mrs. Alexander McDonald have given to the Woman's Medical College of the Presbyterian Hospital in Cincinnati, in memory of their daughter, Mrs. Laura McDonald Stallo, a building just east of the hospital. The building is being put into perfect condition under supervision of the faculty, and will be complete in every respect. The value of the gift will approximate $20,000. It will be known as the Laura Memorial College.

Medical and Chirurgical Faculty of Maryland.—The next annual meeting of this Society will be held in Baltimore, the fourth Tuesday in April, 1896. The president for 1895–96 is Dr. J. E. Michael; the corresponding secretary is Dr. James M. Craighill, both of Baltimore.

Gross Monument.—The statue to be erected to the memory of the late Professor Samuel D. Gross is now under contract, and the artist, Mr. Calder, is at present in Europe with his models, arranging to have it cast in bronze. The models were inspected by Mr. St. Gaudens, the distinguished American sculptor, and approved as being very fine. Congress has appropriated $1,500 for the expenses of the foundation, and authorized the engineer corps of the army to select the site for its erection. The place selected is in the Smithsonian grounds at Washington, near to the Army Medical Library. The statue is to be of standard bronze, representing Dr. Gross holding a scalpel in his right hand and in the act of operating at a clinical lecture. It is to be nine feet high, and upon an appropriate pedestal. The money has all been secured through the joint efforts of Drs. J. R. Weist, W. W. Keen, and C. D. Mastin, representing the American Surgical Association and the Medical Alumni Association of Jefferson Medical College.—*Medical News.*

Society Reports.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, April 15, 1895.

SAMUEL B. W. MCLEOD, M.D., PRESIDENT, IN THE CHAIR.

The Significance of Eye Symptoms in Bright's Disease.—DR. FRANK VAN FLEET read a paper, the full title of which was "The Significance of Eye Symptoms in Bright's Disease, with Some Remarks on the Necessity of a More Rigid Enforcement of the Laws Relating to Medical Practice." We have in the back of the eye, he said, an expanded nerve, in front of which was only a transparent medium, so that changes here could be studied positively during life which, situated in other parts of the body, could only be appreciated by their subjective symptoms. Remembering that changes in the nerves and blood-vessels were often the first evidence of constitutional disease, the importance of studying the eye ophthalmologically became at once apparent.

Nephritic disease influenced the eye externally and internally. The external manifestations, as œdema of the lids, required no special mention. Subconjunctival hemorrhages occurred now and then, but so rarely that he had seen the condition mentioned in only one text-book on diseases of the eye. When present its significance was serious. In one of his cases it was the first symptom to cause the patient to consult a physician, although other evidences of Bright's disease had probably existed a year or more.

The changes in the back of the eye involved the blood vessels and nerves, producing hemorrhages in the former case and nerve inflammation in the latter, termed optic neuritis, retinitis, and neuro-retinitis. In the author's experience, valuable information was frequently derived in optic neuritis by examination of the urine. Inflammation of the optic nerve might exist from uræmic poisoning without for a time causing impairment of vision, while headache and other nervous symptoms might be present. The worst condition was retinitis albuminurica, for optic neuritis might subside without leaving any atrophy, but retinitis albuminurica seldom disappeared without leaving its marks. The condition most often found in the eye in Bright's disease was engorgement of the retina with blood, the nerve more or less swollen, the fundus sprinkled with white patches on a red background. The hemorrhagic spots varied in size from a mere point to a half a pea or larger. When such a condition was seen in the fundus of the eye, the observer should think of the kidneys at once, for it usually indicated Bright's disease near the end. In eighty per cent. of the cases death ensued within a year or two, yet there was a chance when it occurred in acute kidney disease of saving life, but even here a favorable termination would depend upon vigorous treatment. He had seen six cases of retinitis albuminurica not associated with pregnancy the past twenty-two months. All had since died but one, and none of the six patients had known that they had renal disease. Chronic Bright's disease was a most insidious affection. In chronic nephritis, retinitis apoplectica was a fatal symptom, being of much graver significance than when caused by rheumatism or gout, for these affections did not necessarily imply disease of any particular vital organ, and the skin, bowels, etc., would probably rid the system of the effete material. But when the cause was a structural change in the kidneys, the outcome could be predicted with certainty. Vicarious elimination would not subserve the same purpose for any considerable time.

Another symptom in Bright's disease was amaurosis nephritica, or sudden blindness. It might occur without any apparent change in the eye, simply as the result of the action of urea on the visual centres, the generally accepted theory being that the direct cause was cerebral anæmia. It occurred most often in acute disease, and might end in complete recovery.

Dr. Van Fleet then related some cases. Refracting opticians flagrantly violated the law regulating the practice of medicine in this State; they advertised openly to test the eyes and to prescribe glasses. Not being physicians, they knew not the significance of optic neuritis, etc., depending upon Bright's disease, and patients were thus kept from consulting those capable of giving them relief until it was too late. Yet the counsel for the County Medical Society had expressed doubt whether this pernicious practice on the part of opticians made them amenable to the law which prevented druggists and others from prescribing medicine. It was the moral duty of the medical profession to at least warn the public of this danger.

DR. J. BLAKE WHITE said he had seen many cases illustrating the necessity for frequent examination of the urine in order not to overlook Bright's disease, for the urine might be free of albumin during several successive examinations and then show this substance. In considering retinitis albuminurica it was well to bear in mind that its prognostic significance depended in some degree upon the form of kidney disease present. For instance, in cirrhosis of the kidney it pointed to a serious systemic condition and a grave prognosis.

DR. G. H. COCKS mentioned two cases in which the first sign of kidney trouble was failing vision. In neither case had there been headache, vertigo, nor other symptom to show that the patients were not in good physical condition. One was a school-teacher from New Jersey, who had sought advice for failing vision and gave no history of Bright's disease, but ophthalmoscopic examination revealed a characteristic picture, pointing to kidney trouble. He told her to return in two days, but he received a telegram, saying that on reaching home she was seized with a convulsion and never recovered consciousness. The second case was similar and the man died sixty hours after the ophthalmoscopic examination, having up to that time been in apparent good health. The cases showed that examinations of the eyes should be made by physicians, not by refracting opticians.

Retinitis Albuminurica Means Contracted Kidney.—DR. N. J. HEPBURN believed it was the general impression among careful observers that a typical picture of retinitis albuminurica almost always meant that type of Bright's disease known as small, contracted kidney. This made it more important as a diagnostic and prognostic sign. Changes in the eyes had been noted sometimes, however, in the other varieties of kidney disease. Regarding refracting opticians, he did not know how the law was going to help us as long as the fault lay at our own door. It was not infrequent for patients consulting him to have glasses which had no relation whatever to their ocular trouble, and when asked where they got them the reply was, at a refracting oculist's recommended by their family doctor. Under the circumstances the refracting optician was not quite as much to blame as might at first seem. In the end it was rather a good thing for ophthalmologists. If the public could stand it, they could.

DR. MEEK thought that Bright's disease associated with retinitis albuminurica constituted a subject which brought the general practitioner and oculist closer together than any other. There were two clinical pictures in which the general practitioner and eye specialist could be of help to each other. In one the patient complained perhaps of only a little malaise, loss of appetite, and diminished strength, and was unable to guess what was the matter. The doctor prescribed a tonic, but he went on to lose more flesh. The doctor had meanwhile found nothing in the urine. The oculist

was then consulted and found in the fundus evidence of a retinitis albuminuria. The general practitioner now examined the urine regularly and was rewarded with further evidence of Bright's disease. The other clinical picture was that where the patient was taken suddenly ill with nausea and vomiting and loss of sight. It was a case in which the cerebral centre for sight was affected, and sometimes occurred after scarlet fever, confinement, etc.

Medical League Against Unprofessional Methods.—Dr. Brothers read a long list of resolutions adopted at a meeting of medical practitioners in the lower section of the city, March 27th, against unprofessional methods and against those physicians who were guilty of them. It seemed that unprofessional methods of obtaining patients were very common among practitioners, medical institutions, and charitable societies in that section of the city. The resolutions expressed an unreserved and vigorous protest.

Symphyseotomy, with Report of a Successful Case.—The paper was by Dr. Thomas R. Savage, in whose absence it was read by the Secretary, Dr. P. B. Porter. The case was that of a woman in her third pregnancy. The first terminated at the fifth month without difficulty. The second at full term, labor two days; craniotomy. Dr. Savage found the following measurements: External conjugate, 18 ctm.; between the iliac spines, 23.5 ctm.; between the iliac crests, 27.3 ctm.; between the tuberosities of the ischia, 6 ctm.; between the symphysis and coccyx, 8.5 ctm., or nearly three inches. Here was a pelvis decidedly funnel-shaped, normal in measurements at the upper straits, but contracted at the pelvic outlet, transverse diameter of 2.5 inches. He was warned by the obstetrician whom he consulted that no increase in the transverse diameter could be secured by symphyseotomy, but recollecting Jewett's experience he proceeded with the operation. The open method was adopted. The pubic joint was found three-quarters of an inch from the mid-line, which he believed was the common situation. An ordinary bistoury was used to cut the cartilage from before backward. The bones were then found retained in position by the post-pubic fascia, and when this was severed the joint sprung apart an inch and three-fourths with a sudden jump. There was no hemorrhage. Packing with gauze. The separation at the symphysis did not exceed two inches and a half. Forceps were used. The biparietal diameter of the child's head measured three and one-half inches. Dr. Savage did not hesitate to estimate the increase in the transverse diameter at an inch and a half, the separation at the pubic joints being two inches and a half. Careful estimates had shown that the pubic bones could be separated three inches, or, if necessary, three inches and a half, without injuring the sacro-iliac joints. Therefore the fœtus could have been brought out of a considerably narrower pelvis than what existed in his case. Not more than two drachms of blood were lost during the operation. Silkworm-gut sutures were used to close the wound, and the pelvis was supported by a broad band of rubber adhesive plaster. Owing to the œdematous condition, the lower angle of the wound was left open for drainage. Catheterization for two or three days. Convalescence uncomplicated. Patient left the bed after three weeks. At present there was slight mobility between the pubic bones, but not sufficient to interfere with walking or climbing stairs. The child was asphyxiated when born, and quite half an hour was spent before satisfactory respiration was established. This was not uncommon after symphyseotomy, and the operator should be prepared to meet it.

Dr. William T. Lusk said he would occupy the few minutes allotted to him by calling attention to the good work being done in symphyseotomy in Paris, especially by Pinard and his associates. They had shown that the operation was safe when undertaken before the woman had become too feeble. In the hospital there were four deaths in forty-eight cases, and of this number three of the deaths were in four women brought in from outside after having been tampered with by various physicians. Of the women already in the hospital, forty-four, only one died. The future work for the profession was to discover means for correctly estimating the size of the child's head and the pelvic diameters, in order that there might not be delay in the operation.

Dr. Lusk had observed in Paris that certain precautions were taken against hemorrhage, and he regarded it as fortunate that Dr. Savage had met with very little, for in another case his patient might die in consequence of it. The clitoris should be seized, pulled down, thus putting its suspensory ligament on the stretch, which could then be divided, the cellular tissue pushed out of the way with the main vessels, the same done with the cellular tissue behind the pubes, and as a protector against injury to the bladder, etc., introduce a guide which he exhibited. Another instrument which he showed was intended to measure and regulate the amount of separation of the symphysis. The separation should be done by the physician, up to the required point, say two inches and a half, and maintained at that. If left to the expression of the child's head, as done in this country and in Germany, it was liable to cause asphyxia or other mischief. The head could then be allowed to come down without turning or forceps. As full dilatation of the cervix as possible should be obtained beforehand. There being no support anteriorly after symphyseotomy, forceps were liable to make a rent through the vagina up into the bladder. Let an assistant give support anteriorly, and take the precaution to use axis traction when using forceps. The fibrous structures which held the pubic bones together had been shown to be very strong, and should be united by silk suture after the operation, thus securing perfect union and avoiding subsequent waddling, which usually had been present in cases operated upon in this country. In France the symphysis was nearly always in the mid-line, which suggested some error of observation in this country.

Dr. George T. Harrison said he had not yet done symphyseotomy, and thought we needed a larger number of cases and a more varied experience in order to judge of its usefulness. It seemed, however, that hereafter embryotomy on the living child would be an unjustifiable procedure.

Dr. Von Ramdohr, referring to Dr. Lusk's statement, said he had had one case of symphyseotomy followed by perfect bony union as demonstrated by a subsequent labor. He felt that the operation was only for experts with plenty of assistance. It ought not to be undertaken hastily, in primiparæ particularly, for we had not yet means for measuring the child's head accurately, and the labor might be completed without an operation.

Dr. E. E. Tull had recently been in Paris, and mentioned the fact that there in a given time they had had thirty-nine cases of symphyseotomy, whereas never before had there been so many cases of Cæsarean section for an equal period. This would seem to show that symphyseotomy was now being done in some cases which formerly were delivered with high forceps. In Germany the mortality for the children had been very high, and there was much greater danger for the bladder and pelvis than in Cæsarean section. The last-named operation in selected cases gave but little greater maternal mortality, and less fœtal. He believed symphyseotomy had a very limited field; he had never seen a case in which it was indicated.

Dr. Von Donhoff said he had never performed symphyseotomy, but he saw no reason why one should not undertake it who intended to do surgery. It was impossible to become an expert without a beginning. To undertake the operation like a butcher, one might lose his patient from hemorrhage, but with ordinary care hemorrhage could be avoided. Regarding the

line of the symphysis, he had himself frequently seen it to one side of the median line.

The Therapeutic Use of Electricity in the Application of Dry or Moist Heat in the Form of Electro-thermal Asbestos Pad.—Dr. J. W. Moore exhibited an electro-thermal asbestos pad, connected with incandescent lamp wire, for use as a therapeutic agent, more especially as an advantageous substitute for the nasty poultice. This pad could be either dry or moist, the temperature regulated as desired, and could be left on without attention as long as necessary. He thought it would be useful, in cases of collapse, to take the place of hot-water bottles.

Correspondence.

THE THERMOMETER AS AN AID IN THE DIAGNOSIS OF INCIPIENT PHTHISIS.

To the Editor of the Medical Record.

Sir: In the May 4, 1895, issue of the Medical Record appears an article by Charles Wilson Ingraham, M.D., of this city, entitled "The First Symptom of Pulmonary Tuberculosis and its Detection by the Fever Thermometer." That this instrument is one of the greatest auxiliaries to modern medical science I think we may all unreservedly agree with Dr. Ingraham. He then states "that as a diagnostic instrument it approaches more nearly the zenith of its perfection in cases of suspected tuberculosis, and that a rise in temperature of from one-half to one degree occurring two or three times weekly, . . . or an elevation of one-half degree occurring daily at some time during the afternoon or evening for a period of two weeks, should cause a strong suspicion of pulmonary tuberculosis, even though it is the only indication, and if the daily record shows an elevation of one degree for a similar period, a positive diagnosis of tuberculosis is justifiable, and will in ninety per cent. of cases be confirmed at a later period."

I hardly think the doctor will find as many among the members of the medical fraternity who, from their experience in the diagnosis of incipient phthisis, will support him in this view, as he will in his statements concerning the utility of the clinical thermometer. I am well aware that a more or less continued elevation of temperature associated with concurrent symptoms belonging to this disease is a valuable diagnostic point, but that an elevation of temperature of from a fraction to one degree occurring daily in absence of other symptoms can be taken as evidence of pulmonary or laryngeal tuberculosis, I do not think can be substantiated for the following reasons: We are informed by nearly every standard work on physiology (a fact that anyone can demonstrate upon his own body or that of another, and which I have repeatedly observed) that there is a normal diurnal increase in body temperature of from a fraction to one and a half degree, varying with the individual and time of day, such increase occurring after a full meal, and also being higher from 2 to 5 P.M., and in the evening than in the morning or forenoon. This is a perfectly physiological process. Would it, as the doctor says, be rational or scientific to take the temperature of a patient at 9 to 11 A.M., the time at which it should be about 98.4° F., and compare it with a temperature taken at 2 to 4 P.M., the time when the digestive, absorbent, and assimilative functions are most active, thus causing more oxidation and creating an additional heat in the body, or to compare the forenoon temperature with the temperature at 6 to 8 P.M., the time when the eliminative organs are busy throwing off the accumulated waste products of the day, and thus causing a slight elevation of temperature, and conclude that such elevation indicated phthisis? If such an elevation of temperature could be taken as almost positive evidence of the disease in those slightly debilitated, without additional evidence, there would be more cases of cures of pulmonary tuberculosis reported in the next six months than have been reported since the first knowledge of the disease to the present time. Suppose an individual in poor financial circumstances presents himself or herself to a physician, such person being somewhat emaciated and having poor appetite and digestion, yet giving no symptoms upon which a very definite diagnosis can be made, and the doctor, anxious to do his duty by the patient, uses all his medical skill in trying to make something definite out of the case, and finds a slight elevation of temperature every evening for a few days, in addition to the slight departure from normal before mentioned, and nothing more, would a diagnosis of phthisis, with advice to seek a healthier but costlier clime, or a long course of what the doctor might be pleased to term "anti-consumptive" treatment, but which would mean many dollars to his patient, be rational, scientific, or just treatment? Would it not be more wise and conservative to regulate the secretions and administer tonic digestive remedies, and advise a little rest at home for a time, instead of making a diagnosis of a disease so deceptive in its manifestations that the very best diagnosticians are often deceived and unable to say whether a given case is tuberculosis or not until the disease has made further progress. A large per cent. of such cases, under simple tonic treatment, as before mentioned, regain their usual health, and yet, had their temperature been taken as an indication of phthisis, nearly all of them would have been found to be suffering from tuberculosis, according to Dr. Ingraham's method of diagnosis.

Perhaps this is the reason the doctor has found that this is "the most promising period to treat the disease." I fully agree with him here, but am as fully convinced that the cases which recover by rational treatment at this time are not tubercular in any sense of the word, and that their diurnal increase in temperature is not due to the presence of the tubercle bacillus, but is obeying a law which is in every sense of the word physiological. It has been my experience, which I think is also true with most physicians, that cough is a much more frequent symptom of incipient phthisis than almost any other symptom, and especially is this true as compared with elevation of temperature, and as the tubercle bacillæ are the cause of both (excluding normal rise in temperature) it seems logical that such should be the case for the following reasons: The bacillæ gain entrance to the lung tissue, proliferate, and because of irritation of the minute peripheral nerve endings, and the slight inflammation of the mucous membrane which their presence excites give rise to the little, dry, hacking cough with which we are all so familiar; this occurs before the bacillæ have multiplied in numbers sufficient to poison the blood by their ptomaines, and caused involvement of lung tissue to a degree sufficient to cause an elevation of temperature which we can take as anything like definite or accurate data upon which to base a diagnosis of phthisis when we take into consideration the diurnal variation in temperature. When the disease has made progress to such an extent that we can exclude the normal variation, and fairly call the temperature abnormal, physical signs and objective symptoms have made their appearance to such an extent that the disease may be recognized by a score of other manifestations which are more reliable than the "temperature test." I would not depreciate the value of the clinical thermometer, and I do not believe that a physician can be found without one at the present day (unless he be a mental morbid curiosity); yet, when I consider the fact that many of the grand old physicians, some living and some dead, practised so many years and so successfully without them, I sometimes think that there are times when we are governed too much in our treatment of many cases by

what the thermometer indicates, and lose sight of other conditions as indicated by other means, and all because of too much enthusiasm over our clinical thermometer.

RAY BEARDSLEY, M.D.

BINGHAMTON, N. Y., May 31, 1895.

THE DIAGNOSIS OF CHRONIC DISORDERS OF THE STOMACH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: in your issue for June 1, 1895, there is an article by Dr. H. Beck, entitled "On the Diagnosis of Chronic Disorders of the Stomach," which calls for rather severe criticism. The writer frequently speaks of the stomach-pump. I suppose he means the siphon. I myself have frequently used the stomach-pump, but that was twenty-three years ago, at the time when it was first introduced by Kussmaul, but never since, that is never since the siphon method was substituted. To-day, I presume, we consider the stomach-pump as only of historical interest.

The illustrations which the author gives of errors in diagnosis in regard to ulcer of the stomach are rather inaccurate. Some of the striking clinical symptoms which lead us to suppose the presence of ulcer are not mentioned.

Among other things the author says that a good deal of patience is necessary on the physician's part to evacuate the stomach in its empty state. We will all agree with him in this assertion.

I am at a loss to understand why he prefers tropæolin to the much better congo red test.

Dr. Beck speaks of the presence of HCl in ulcers of the stomach, not mentioning that in exceptional cases this acid may be wanting. The very characteristic circumscribed pain on pressure on the epigastrium is not mentioned, nor are the bloody stools with their pitch-dark color, both such very characteristic diagnostic symptoms of ulcus ventriculi, enumerated.

The author has not deemed it worth while to speak of the presence of lactic acid in carcinoma of the stomach, which Boas has claimed to be one of the early diagnostic symptoms, but about which there has been a great deal of controversy in recent literature.

However, the chapter on carcinoma ventriculi is completed in a very few lines, and not even the absence and presence of HCl in connection with this disease is mentioned.

Again, the histories of acid catarrh of two pregnant women are so inaccurate and incomplete that they have no value whatever.

The author complains that the subject of the capacity of the stomach receives a stepmotherly consideration at the hands of the private practitioner. But the private practitioner, I think, is quite correct in sparing the patient the trouble of this—in most cases—unnecessary and not always exact measurement of the capacity, that is, of the amount of liquid or air the organ is able to hold. It is of paramount importance to know the dynamic capacity of the stomach, and this can never be learned by simply measuring the size of the organ.

The procedure which Dr. Beck gives as a novelty, namely, to determine the lower limit of the stomach, and the apparatus which he calls gastro-meter are by no means new. This method was described in 1878 by J. W. Neubauer in an article in the *Prager Medicinische Wochenschrift*, entitled "Beiträge zur Beurtheilung der Capacität des Magens," and can be found described in any text-book on diseases of the stomach; for instance, in Boa's "Diagnostik und Therapie der Magenkrankheiten," 1. Theil, 3. Aufl., S. 104.

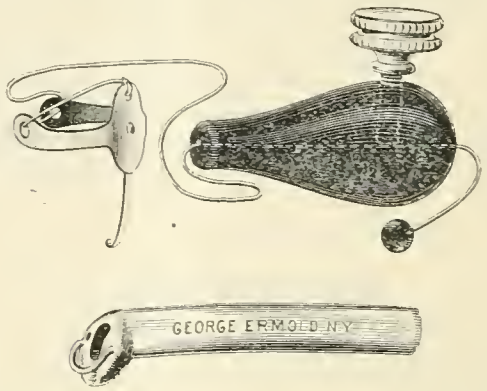
A. ROSE, M.D.

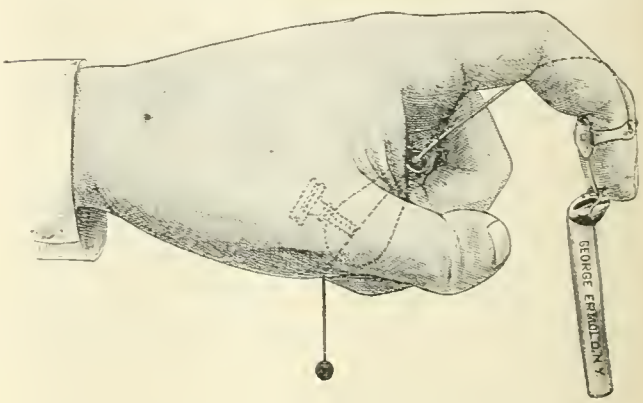
336 EAST FIFTEENTH STREET, NEW YORK.

REMOVAL OF INTUBATION TUBES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The device for removing intubation tubes described in the MEDICAL RECORD of June 15th is so similar to one that I have been using at the New York Polyclinic for the past three months, and which I presented to the Harvard Medical Society on May 25th, and the American Pediatric Society, at Hot Springs,





Va., on May 27th, that I hope you will find space for these cuts, which illustrate the principle of my extractor very well. They are made by Mr. George Ermold, of New York.

Yours truly,

DILLON BROWN, M.D.

Supra-pubic Cystotomy for Calculus.—Dr. A. H. Meisenbach (*Journal of American Medical Association*) sums up a paper on this subject with the following conclusions: 1. That the transverse incision is more easily executed from a technical stand-point. 2. That it affords more space in which to work in the depths of the wound than the median incision, and hence is superior for any exploration of the bladder, for whatever condition. 3. That there is less liability to injury of the peritoneum, because the knife is used parallel with and on a level below its lowest fold. 4. That it is unnecessary to inflate the rectum. 5. That it is unnecessary to inject the bladder, and consequently, the risk of injury to the organ is avoided, which in the aged is an element that should always be considered. 6. That the catheter in the bladder is a safe guide to the location of the fundus and anterior wall. 7. That with the catheter as a guide, the bladder can be incised with ease and facility.

The Salicylate of Sodium in Ophthalmia.—A solution of the salicylate of sodium, of the strength of ten grains to the ounce and upward, is highly recommended by an occasional contributor as a collyrium in simple ophthalmia. When frequently applied the effects are quickly manifested.—*New York Medical Journal.*

INDEX.
